So physicians have come to believe that a definite antibody to morphin is formed in the blood, and that the unneutralized antibody is the cause of the withdrawal symptoms. Another explanation sometimes offered for the occurrence of the withdrawal symptoms is that morphin disturbs the normal secretory and excretory functions of the body, and by its prolonged use thus induces an autotoxemia. But it is by no means clear why this toxemia should suddenly fulminate when the morphin is withdrawn, and the lack of explanation on this point materially weakens this theory.

But whether there is present an antitoxin or an autotoxin, it is evident that some form of toxin is present, and the withdrawal symptoms of sweating, vomiting, and diarrhea would indicate that the body is endeavoring to eliminate it.

CUSTOMARY METHODS OF TREATMENT

The present treatment of chronic morphinism involves three principles, *namely,* catharsis, the rapid or gradual withdrawal of the drug, and the administration of belladonna or alkaloids derived from the belladonna group—the alkaloid most generally used being scopolamin. The purpose of catharsis is, of course, to effect an elimination of the toxins. The purpose of withdrawal of the drug is obvious. The purpose of the alkaloids seems to be to effect a stupor or intoxication and thus reduce the suffering caused by the withdrawal symptoms. Various other explanations are offered for the use of belladonna and the alkaloids, one being that the active principles of the belladonna group are physiologic antidotes capable of "unpoisoning" the patient. The explanation of "unpoisoning" seems a little fanciful.

With almost any form of treatment the patient suffers to some extent from the withdrawal symptoms of nervousness, restlessness, leg pains, nausea, vomiting, etc., and following the treatment there is a more or less protracted period of nervousness and insomnia. During the treatment, delirium may develop from the belladonna or scopolamin.

The Towns-Lambert treatment combines catharsis with the rapid reduction of morphin and the hourly administration of a mixture of belladonna, hyoscyamus and xanthoxylum.[1] Catharsis is effected with 5 grains of blue mass and five compound cathartic pills. When the bowels have moved freely, the patient is given two thirds or three fourths of his daily dose of morphin, and his initial dose of the belladonna mixture, which is given thereafter every hour through the day and night in increasing doses. Ten hours after the morphin has been given, the pills and blue mass are repeated, and when free catharsis has been effected, the patient is given one half of his former dose of morphin. In another ten hours the cathartics are again repeated, and after further free purging, the patient is given his morphin with the dose once more cut in half. This is the patient's last dose of morphin. Soon afterward there appears from the cathartics a characteristic green stool, and with its appearance the belladonna mixture is stopped and the patient is given castor oil to cleanse the intestinal tract. The treatment here sketched is modified to suit varying conditions.

The Sceleth treatment involves initial catharsis with the subsequent administration of a solution the chief ingredients of which are scopolamin and ethylmorphin hydrochlorid. The solution is tapered off toward the end of the treatment.

The Petty treatment involves catharsis, rapid reduction of morphin, and the administration of scopolamin.

The Sceleth and Petty treatments thus supplement catharsis and withdrawal by *narcosis.* The Towns-Lambert treatment supplements catharsis and withdrawal with a belladonna mixture that is given empirically and is supposed in some manner to relieve the craving for narcotic drugs. The treatment is presumed to relieve the craving for alcohol and tobacco as well as for morphin.

It is difficult to determine the value of the belladonna mixture of the Towns-Lambert treatment. Relative to this matter I can say that I have seen morphinists smoke constantly throughout the treatment when they have not expected to lose their appetite for tobacco, and I am convinced that none of them would voluntarily have given up morphin if they had expected to relinquish only their cigars. I am inclined to believe that suggestion is one of the secret ingredients of the belladonna mixture.

In thus criticizing the Towns-Lambert treatment, however, I do not mean to discredit it. The treatment possesses unmistakable merit, and I am sure that suggestion cannot eliminate toxins from a morphinist's blood stream. Possibly the toxins are neutralized to some extent by the belladonna mixture, and probably they are eliminated to a large extent by catharsis. Elimination would appear to be of special value for the reason that the withdrawal symptoms of sweating, vomiting and diarrhea represent an attempt at elimination by nature.

At any rate my faith has been largely in elimination, and the idea suggested itself to me that elimination could be greatly augmented by giving the patient intravenous infusions of physiologic sodium chlorid solution, for this solution would be eliminated by the kidneys and intestine, and should carry the toxins with it.

Another apparent advantage of the intravenous solution is that it would dilute the toxins of the blood stream. To illustrate this mathematically: A man weighing 140 pounds would have approximately 7 pints of blood, and an intravenous infusion of 2 pints of saline solution would dilute the toxins of the blood to approximately three fourths of their original concentration. From this dilution of the toxins one would expect to see an amelioration of the withdrawal symptoms. The dilution would, of course, be temporary, for additional toxins would pass to the blood stream from the body tissues, but these toxins would in turn be eliminated with the excess fluid.

AUTHOR'S METHOD OF TREATMENT

On these purely theoretical considerations I decided to attempt the treatment of chronic morphinism solely by elimination, supplementing a catharsis of the intestinal tract with a catharsis of the blood stream brought about by repeated intravenous infusions.[2] The patients were volunteers treated gratuitously at Mount Airy Sanatorium through the generosity of the superintendent, Dr. George E. Neuhaus.

The treatment of a case is typically as follows: The patient is put to bed and his morphin stopped entirely. He is put on a semisolid or a liquid diet, and is given cathartics as prescribed in the Towns-Lambert treatment. He thus receives three or four cathartic courses, consisting of 5 grains of blue mass with five compound cathartic pills, at intervals of approximately eighteen hours. Some hours after the last of these cathartic courses he is given castor oil. The patient receives from two to four intravenous infusions a day according to his condition. The standard infusion consists of 1,000 c.c. of 0.9 per cent. sodium chlorid in sterile freshly distilled water.

During the first few days of treatment the patient is given enough chloral, usually about 30 grains, at bedtime to insure a night's sleep. Hypnotics are an important element in the treatment, for the sleep they induce not only blots out large periods of discomfort, but

---

[1] The mixture consists of:

	Gm. or C.c.	
Tincturae belladonnae (15 per cent.)	62	fl ℥ ij
Fluidextracti hyoscyami	ãã 31	fl ℥ i
Fluidextracti xanthoxyli		

[2] The infusions were given from quart medicine bottles hung in an inverted position. A two-hole rubber stopper carries a short glass tube as an outlet for the solution, and a long tube reaching to the bottom of the bottle serves as an air inlet.

also fortifies the patient mentally and physically for the ordeal through which he is passing.

The semisolid or the liquid diet is continued as long as the patient feels any nausea, and he is kept in bed during the cathartic period and until all acute discomfort from the withdrawal of the morphin has disappeared.

As previously stated, the morphin is stopped entirely, and if at any time the patient complains unduly of his withdrawal symptoms, he is given a saline infusion instead of a hypodermic injection of morphin.

There seem to be no contraindications to the saline infusions, and patients have suffered no ill effects from receiving three or four infusions daily for a period of a week or more. One patient received infusions in thirteen days amounting to 50 per cent. of her body weight, and her physical condition improved greatly during this period.

The infusions do not produce a marked increase of arterial tension. An infusion of 1,000 c.c. is followed by an increase in blood pressure equivalent to about 5 mm. of mercury. The increase is of course temporary.

The repeated infusions do not produce anemia. There is a slight decrease in the red cell count and percentage of hemoglobin owing to the increase of the fluid element of the blood, but there is no destruction of the blood cells. The absence of anemia is clearly evidenced by the patient's marked improvement in color.

The infusions are followed by a marked decrease in the viscosity of the blood. The decreased viscosity lessens capillary resistance, and thus reduces the normal heart load. This is advantageous in reducing the tendency to cardiac weakness so often seen with the withdrawal of morphin. It is also advantageous in permitting the administration of large doses of chloral without embarrassment to the myocardium. It was not found necessary to give any of the patients cardiac stimulants.

Six patients were treated by the foregoing method. Their average age was 34 years. Their average period of addiction was twelve years, and their average daily dose of morphin, 7 or 8 grains. Three of them were addicted to the occasional use of cocain, and three of them had positive Wassermann reactions. The average patient was fourteen days in the sanatorium, and he received infusions during the first seven days. The average amount of saline solution administered to each patient during this period was 15,600 c.c. The average patient experienced discomfort from the withdrawal symptoms at different intervals during the first two or three days, but none of them can be said to have been markedly uncomfortable at any time. Most of them experienced considerable relief from the intravenous infusions, and thus the periods of discomfort preceding the infusions would amount to only a small total. After the stage of acute discomfort there followed a period of nervousness and sleeplessness. This nervousness was not constant, but manifested itself at occasional intervals for several days. The sleepnessness was not protracted, and the average patient took hypnotics for only four nights.

During the restless convalescent period, two of the patients were given the Towns-Lambert treatment (without morphin) as an experiment. Both of the patients had been addicts for more than twenty years, and their nervousness persisted at the end of the second week, at which time the Towns-Lambert treatment was given. The nervousness diminished considerably following this second treatment. Their improvement would point to some specific potency in the Towns-Lambert belladonna mixture, though in reasoning from cause to effect one must consider also the probable efficacy of a second course of cathartics, and also the influence of suggestion. Suggestion may have been quite a factor with these patients, for they knew the Towns-Lambert treatment to be fully accredited and the infusion treatment to be merely experimental.

In addition to the six patients treated by infusions, another six were given the Towns-Lambert treatment simultaneously with the infusions. Before the Towns-Lambert treatment was begun, the patients were placed under observation for twenty-four hours, and during this period were given small doses of morphin as their condition required in order to determine the minimum twenty-four hour dose necessary to keep them comfortable. The rapid reduction in accordance with the Towns-Lambert treatment then followed with this amount as a basis.

The six patients in this series were milder cases than those treated only by infusions, and some of the subjects were private patients at Mount Airy Sanatorium. Their average age was 40; their average period of addiction was nine years; and their average daily dose of morphin was 3½ grains, this dose being one-half the amount in the first series. Four of the patients occasionally used cocain. Two of them had positive Wassermann reactions.

The first two patients received infusions only when they manifested discomfort under the Towns-Lambert treatment. The remaining four received infusions from the start. The average patient was given five infusions, and in the average case the infusions were not continued beyond the third or fourth day. The average patient was discharged on the seventh day.

With this combination of the Towns-Lambert treatment and the infusion treatment the patients suffered about the same discomfort from the withdraw symptoms as those treated by infusions alone, but they recovered more quickly from the subsequent period of nervousness. Some of them manifested a definite euphoria on the third or fourth day, and stated that they had never felt better in years. Thus it would seem that the infusion treatment combined with the Towns-Lambert treatment is better than the infusion treatment alone; but in order to determine the matter definitely it would be necessary to take two equivalent series of cases instead of two series of rather dissimilar cases such as I employed in my experiments.

I give here a brief summary of the individual cases of the two series:

SERIES I. PATIENTS TREATED BY INFUSIONS AND CATHARSIS

The patients in this series of cases were treated by infusions and catharsis, and their morphin was stopped entirely. When necessary they were given hypnotics during the first few days to combat insomnia. They were kept on semisolid or liquid diet while there was any tendency to nausea, and were kept in bed till all acute discomfort had subsided.

Case 1.—A woman, aged 27, had used morphin for eight years, and was taking 8 grains a day hypodermically when presenting herself for treatment. The Wassermann test was strongly positive. She received seventeen infusions (each of 1,000 c.c.) during eight days of treatment. The first four days she received 30 grains of chloral, or 15 grains of chloral with 15 grains of sodium bromid, at bedtime.

On the first day of treatment the patient was comfortable. On the second day she was restless during the afternoon and evening, and she vomited once or twice during the evening. On the third day she was restless and nauseated during the early morning, but she slept for several hours after receiving an infusion. She was restless again during the afternoon. After the third day she was allowed to be up and around. She felt a little nervous during the afternoons of the fourth and fifth days, but the nervousness was relieved by hot baths. After the fifth day she was free from nervousness, ate ravenously and slept well. She was discharged the twelfth day.

Case 2.—A man, aged 32, who had used morphin for eleven years and was taking 8 or 10 grains a day hypodermically, was given ten infusions over a period of five days. The first night he received 30 grains of chloral. The third night he received 15 grains. No hypnotics were administered the second night, or any night subsequent to the third. He had no trouble at any time with insomnia.

The patient was restless and nauseated during the evening of the first day, and vomited once or twice. He slept the greater part of the second day, and fell asleep while taking an infusion. He was comfortable on the third day, but on the fourth day felt nauseated after taking solid food. He was kept on a light diet for another couple of days, and had no further nausea or other discomfort. He was discharged on the thirteenth day.

Case 3.—A physician, aged 37, who had contracted the morphin habit at 24, and had undergone several cures and several relapses, and occasionally used cocain, took his last cure seven months before entering the sanatorium, but one month before had recommenced the use of cocain and morphin. When admitted for treatment he was using 15 or 20 grains of cocain and about a grain of morphin daily.

He received a total of ten infusions in four days, and was given hypnotics the first three nights. He had some discomfort from nausea and leg pains on the second day, and was restless at times on the third day. He was discharged on the fifth day.

Case 4.—A man, aged 43, had used morphin for twenty-four years, and was using 8 grains daily hypodermically when he presented himself for treatment. He was addicted to the occasional use of cocain. The Wassermann test was strongly positive.

With this patient the treatment was unnecessarily prolonged owing to the fact that he surreptitiously obtained morphin on the seventh day. He was a charity patient taking treatment under more or less pressure, and was never very wholehearted about giving up his morphin.

He received seventeen infusions during the first eight days, and four infusions on the four succeeding days. He received hypnotics only once—on the day following his self-administered dose of morphin. He was never markedly uncomfortable during the entire treatment, and he had no insomnia. His chief difficulty was a tendency to nausea and vomiting on taking solid food, and he was accordingly kept on liquid diet for a week. After the first day he frequently asked that his infusions be postponed, as he was feeling comfortable. But despite the fact that he evinced no acute withdrawal symptoms, he frequently complained of nervousness and restlessness. At the end of his second week he was therefore given a morphinless Towns-Lambert treatment as a matter of experiment. He showed considerable improvement after this treatment. He was discharged at the end of three weeks.

Case 5.—A woman, aged 40, had used morphin for twenty years, and was taking from 8 to 12 grains a day hypodermically. She used cocain occasionally. The Wassermann test was strongly positive.

She received twenty infusions during the first eight days, and five infusions during the succeeding five days. The first five days she received 30 grains of chloral at bedtime. After this the hypnotic was tapered off, and during the following week the patient was at times troubled with sleeplessness.

On the first day of treatment the patient was entirely comfortable. On the second day she had definite withdrawal symptoms: restlessness, leg pains, nausea and vomiting. The same symptoms were present, though in a less degree, on the afternoon of the third day, but they were considerably relieved by the infusions. The patient had no acute withdrawal symptoms after the third day, but each afternoon she complained of nervousness and restlessness. The nervousness was relieved by hot baths, but as it continued to recur each afternoon, the patient was given a morphinless Towns-Lambert treatment at the end of two and a half weeks. She improved after this treatment, but was still restless at times. As stated, the patient had a positive Wassermann reaction, and it is possible that her malaise may have been partly due to her syphilitic condition. She was discharged at the end of three and a half weeks.

Case 6.—A man, aged 27, who had used morphin for seven years, and was taking 10 grains a day hypodermically, received eleven infusions in four days. He was given hypnotics the first four nights. He was restless during the afternoon and evening of the second day, but had no acute withdrawal symptoms. He seemed quite comfortable at all other times, and was often singing and whistling. He was discharged at the end of a week.

SERIES II. PATIENTS TREATED BY TOWNS-LAMBERT METHOD AND SALINE INFUSIONS

The patients in this series were given the routine Towns-Lambert treatment supplemented by saline infusions. Before treatment was begun, a patient was kept under observation to determine the minimum amount of morphin necessary to keep him comfortable for a twenty-four hour period. The initial dose then given with rapid reduction was two thirds of this minimum amount. Hypnotics were not necessary during the course of the Towns-Lambert treatment, since the patient was receiving morphin, and they were hardly practical, since the patient had to be disturbed every hour to receive his belladonna mixture.

Cases 1 and 2.—These two patients were men in their forties who had used morphin for about a year and were taking only 1 or 2 grains daily.

They were given the routine Towns-Lambert treatment, which was supplemented by two infusions during the last six or eight-hour period, this period being marked in both cases by considerable discomfort. The discomfort was not greatly relieved by the infusions, but on the following day both patients were in excellent condition and remarked on their well-being. Both patients were discharged on the fifth day.

Case 3.—A man, aged 41, had used morphin for fifteen years and during this period had undergone several cures and several relapses. At times he indulged in cocain. When he presented himself for treatment he was using 8 grains of morphin a day by hypodermic injection.

The initial dose of morphin given in the Towns-Lambert treatment was 3 grains. He received nine infusions during the first five days of treatment.

On the second day the patient was restless for several hours before receiving his last dose of morphin. On the third day he was extremely nervous and uncomfortable during the latter part of the afternoon and early evening. He was then given 85 grains of chloral in broken doses, following which he slept intermittently through the night. After the third day he had no discomfort, and hypnotics were necessary only once subsequently. He was discharged the fifth day.

Case 4.—A man, aged 26, who had used morphin for two and a half years, and was using 4 or 5 grains daily by hypodermic injection, and who occasionally used cocain, was given the Towns-Lambert treatment with an initial dose of 1½ grains of morphin. He was given seven infusions in four days. He showed no marked distress at any period of the treatment, though he was restless at times during the first four or five days. He had no difficulty from sleeplessness. He was discharged at the end of two weeks.

Case 5.—A woman, aged 40, had used morphin for twenty-two years, and was taking 3 grains daily by hypodermic injection when she presented herself for treatment. Occasionally she used cocain. The Wassermann test was strongly positive.

The patient was given the Towns-Lambert treatment with an initial dose of 1 grain of morphin. She received five infusions in three days.

The first night and the morning of the second day were marked by discomfort with some nausea and vomiting. (The patient was probably started with too small an initial dose of morphin.) The afternoon and evening of the second day were tolerably comfortable, though the patient at times complained of nausea. She managed to sleep the second night between her belladonna capsules. She was nervous and restless the third day, but experienced no acute withdrawal symptoms. She was given 15 grains of chloral and 15 grains of sodium bromid at bedtime, but spent a rather wakeful night. After the third day the patient had only one period of nervousness, this being on the fourth evening. She was given no further hypnotics. She was discharged the sixth day.

Case 6.—A woman, aged 52, had used morphin for fifteen years, and was using 3 grains daily by hypodermic injection. At times she used cocain. The Wassermann test was strongly positive.

The patient was given the Towns-Lambert treatment with an initial dose of 1 grain of morphin. She received five infusions in three days. She was nervous and restless during the latter half of the second day. She was also nervous on the third day. There was some nausea accompanying the nervousness, but the patient vomited only once or twice. Her discomfort was considerably relieved by the infusions. She was given hypnotics on the third evening, but afterward slept well without them. There was no discomfort after the third day. The patient was discharged on the sixth day.

BROADER ASPECTS OF MORPHINISM

We should bear in mind that 75 per cent. of morphinists have contracted their habit through the careless administration of morphin by physicians; consequently they are by-products from the practice of the medical profession. A majority of the remaining 25 per cent. owe their habit largely to the former careless sale of morphin consequent on government negligence.

In regard to the present position of the morphinist: When the Harrison Narcotic Act came into force in March, 1915, it automatically stopped the supply of morphin available to addicts through legitimate channels. It did not stop the morphinist's physiologic need for the drug, however, and it did not provide medical treatment to remove this need. Consequently, while beneficent in its intent and doubtless beneficent in its ultimate and total result, the act imposes unwarranted suffering on existing addicts.

Even the victims of the morphin habit are entitled to a square deal, and it would seem that the least that could be done to alleviate their misery would be to register them and license them to receive their morphin at the hands of a duly authorized physician or government agent. Such a procedure would have the additional advantage of stopping the illicit traffic in morphin.

It would be better to cure these addicts, however, than to license them; and they must be cured in order to be reformed, for their disability is more physical than moral. They were neither cured nor reformed with the enactment of the Harrison act; they were merely designated as the prey of illicit dealers. These dealers create more morphinists; and by their extortion they impel their victims to prostitution and crime. Thus they bring confusion into the reforms originally purposed by the Harrison act.

AND
THOMAS M. RIVERS, M.D. (Baltimore)
First Lieutenant, M. C., U. S. Army
CAMP PIKE, LITTLE ROCK, ARK.

The existence of an epidemic of influenza at Camp Pike was recognized when 214 cases of influenza were admitted to the base hospital, September 23. The epidemic was foreshadowed by a steady increase in the number of admissions to the base hospital diagnosed as acute bronchitis. This increase began about September 1, and on September 18 there were fifty admissions with this diagnosis.

Beginning September 23, the number of cases showed a sudden and alarming increase. September 27, there were 1,037 new cases, and the number continued in the neighborhood of 1,000 a day until October 3, when the final decline began. During the period from September 20 to October 19, there were 11,899 cases of influenza. Table 1 gives the number of cases of influenza by days from September 1 to October 31, including those cases diagnosed as acute bronchitis during the first part of September, and also the number of cases of pneumonia having onset on each day.

During the two months covered by the table there occurred 12,393 cases of influenza and 1,499 cases of pneumonia. Only two patients died with a diagnosis of uncomplicated influenza (not confirmed by necropsy), while of the patients with pneumonia, 466 died. Of the patients with influenza, therefore, 12.1 per cent. developed pneumonia, and the mortality for pneumonia was 31 per cent. The mortality for the epidemic as a whole was 3.8 per cent. of those attacked by influenza.

The most striking feature of the epidemic was the extremely rapid spread of the infection throughout the camp. Starting September 22 in a regimental area situated in the extreme southwestern corner of the camp, the disease had within four days appeared throughout the camp proper, and four days later appeared in two outlying encampments, situated respectively 1 mile north and 3 miles east of the main camp.

No single organization escaped the infection, and during the thirty days from September 20, 23.3 per cent. of the total population of the camp suffered from the disease. The figures given herewith are based on a detailed study of 11,725 cases occurring between September 20 and October 14, and comprise practically the whole of the epidemic.

The disease displayed a striking selective incidence among the men who had been in camp less than one month. During the period from August 20 to October 1 there had arrived in camp 23,216 new men, and during October 553 additional men arrived. Among these new men there developed 7,268 cases of influenza, an attack rate of 30.6 per cent. There were in camp, October 1, 28,782 men who had been in camp prior to August 20. Of these, 4,462 developed influenza, an attack rate of 15.5 per cent., or almost exactly half the attack rate of the new men. This disparity between the attack rates of old and new men was true of both white and colored men.

As between white and colored men there were marked and interesting differences in the rates of attack. The total exposed population, including those in camp October 1, and those arriving during October, was 52,551 men, of whom 41,778 were white and 10,773 were colored. The white men developed 10,296 cases of influenza, a rate of 24.6 per cent., while the negroes developed 1,429 cases, a rate of 13.3 per cent.

That this difference in susceptibility is not due to any essential racial immunity is shown by the experience of a draft of 1,954 negroes who arrived in camp between September 23 and 28. Of these men, 1,860 were transferred between September 27 and September 30 to the negro tent colony at Fort Roots. In this camp at the time of their arrival there were 2,130 negroes, most of whom had been in camp six weeks or longer. There had been no recognized cases of influenza in this camp prior to the arrival of the new draft. September 30, one of the new men developed influenza, followed on the next day by forty-seven cases among the new men, and on the next, October 2, by 462 cases, including a considerable number among the old men. Between September 30 and October 14 there were 972 cases of influenza in the camp, with 107 cases of pneumonia. Of the 972 cases, 810 were in the men of the new draft and 162 in the old men in camp. The rate of incidence for the new men was 43.6 per cent., about as high as that of any organization in Camp Pike, while that of the old men was 7.6 per cent., approximately equal to that of negroes of similar length of service in Camp Pike.

* Cases in parentheses, admitted with diagnosis of acute bronchitis.

The time of development of pneumonia in relation to influenza is shown in the table. In general, the peak of the curve of pneumonia followed approximately one week after that of influenza, although the highest single day for both coincided. The general incidence of pneumonia followed that of influenza, and the preponderance of new men among the pneumonia cases was even more striking than among the influenza cases. Of the pneumonia patients, 1,006, or 67.5 per cent., were new men, while 62 per cent. of the patients with influenza were new men. The rates of incidence of the two diseases in old and new men are given in Table 2.

TABLE 2.—INCIDENCE IN OLD MEN AND NEW MEN

	Population	Influenza		Pneumonia	
		No.	Per Cent.	No.	Per Cent.
Old men	27,782	4,462	15.6	493	1.7
New men	23,769	7,263	30.6	1,006	4.2
All men	51,551	11,725	22.7	1,499	2.9

Of the new men with influenza, 13.8 per cent. developed pneumonia, as against 11 per cent. of the old men.

The incidence of pneumonia in cases of influenza was much higher among the negroes than among the whites. Of 10,296 white patients with influenza, 12.7 per cent. developed pneumonia, while among 1,429 negroes with influenza, 283, or 19.8 per cent., developed pneumonia. The rate of fatality from pneumonia was slightly higher in white men than in negroes. Of 1,216 white pneumonia patients, 386, or 31.7 per cent., died, while of 283 negro pneumonia patients eighty, or 28.2 per cent., died.

September 24, the base hospital contained 2,789 patients; the hospital had been planned to care for 2,009 patients. From September 24 to 30 from 188 to 486 patients were admitted daily to the hospital, so that on September 30 the hospital contained 3,587 patients. October 5, the number of patients reached the maximum, 4,233. September 24, by order of the camp surgeon the milder cases of influenza were treated in barracks. Every agency for the receiving, the housing and the care of patients throughout the camp was strained by a demand far beyond that for which it had been planned. Patients were crowded in the infirmaries, in the ambulances, in the receiving room of the hospital, in the wards and even in corridors between the wards, where it was essential to shelter them. It was necessary to open and organize in great haste, with inadequate equipment, wards for the receipt of patients with pneumonia. The medical personnel of the hospital was large at the time; the nursing corps was organized for the care of 2,440 patients; one quarter of them (sixty-two of 240) were attacked by influenza.

The pressing need of diminishing the overcrowding of the hospital was immediately recognized by the commanding officer, and through the authorities of the camp, barracks previously used by three replacement regiments about a quarter of a mile distant were placed at the disposal of the hospital. Patients were moved from the overcrowded hospital into this annex as fast as the facilities available permitted. October 3, 523 patients were transferred to the annex; on the 4th, 452; on the 5th, thirty-two, and on the 6th, 387. In the main hospital, twenty wards for patients with pneumonia were added to the two that already existed. The installation of cubicles and other necessary measures required some time, and during the early period arrangements for the care of patients with pneumonia in some of the new wards were necessarily wholly unsatisfactory. With relief of overcrowding, conditions rapidly improved. The influence of overcrowding on pneumonia will be discussed later.

INFLUENZA

The influenza that has occurred here has been characterized by sudden onset with chilliness and sharp elevation of temperature, often from 103 to 105 F. There has been extreme prostration, severe backache, suffusion of the face, and injection of the conjunctivae. Coryza, pharyngitis and tracheitis with a harrassing cough have been almost invariable; epistaxis and slight hemoptysis, frequent. In the majority of cases the temperature has subsided after from two to five days, usually rather abruptly. About one third of the patients have developed purulent bronchitis.

Search has been made for *Bacillus influenzae* in a group of twenty-three patients from one to six days after the onset of the disease. From each individual a culture on blood agar (5 per cent. horse's blood in meat, infusion agar) has been made (*a*) from the nose, (*b*) from the throat and (*c*) from sputum; and (*d*) sputum has been injected into the peritoneal cavity of a white mouse.

* The interrogation point indicates that the plate was contaminated.

Multiple cultures have demonstrated in some instances in almost pure culture the presence of *B. influenzae* in all of these cases of early influenza. Passage of sputum through the white mouse has proved the most effective means of demonstrating the organism; cultures from the sputum or throat have been nearly as effective. There is some difficulty in demonstrating the organism in consequence of the minute size of colonies, which may be wholly overlooked by those not familiar with its cultural characters, in the presence of other organisms; for example, in the zone of hemolysis of the hemolytic streptococci the colonies become conspicuous.

BRONCHITIS WITH INFLUENZA

A considerable number of those attacked by influenza develop bronchitis. Of 103 influenza patients kept under observation, thirty-six had purulent bronchitis. The sputum is profusely mucopurulent and sometimes streaked with blood. In these cases numerous moist râles may be heard. The sputum on direct smear or on culture almost invariably shows *B. influenzae*, often in great numbers.

In attempting to establish the relation of *B. influenzae* to influenza and its complications, we have borne in mind the observation made at Camp Funston that *B. influenzae* was found in the mouths of 35.1 per cent. of all healthy men examined and was present, in the absence of an epidemic of influenza, in the sputum of a very large proportion of those suffering with bronchitis. Our observations here have shown that the organism is invariably present in the upper respiratory passages of patients with influenza.

PNEUMONIA WITH INFLUENZA

Pneumonia has occurred in 12.1 per cent. of all influenza patients in this camp, and all pneumonia patients have been treated in the base hospital. Among 103 influenza patients selected for observation from the onset of influenza, four developed clinical evidence of bronchopneumonia and three of lobar pneumonia.

The clinical features of pneumonia following influenza may be best described by division into three groups. It should be borne in mind, however, that the picture has been a complex one and that correct clinical interpretation is not always possible, since many cases do not conform sharply to any one type. These groups are: (1) bronchopneumonia; (2) lobar pneumonia, and (3) lobar pneumonia with purulent bronchitis.

In the first group, bronchopneumonia has usually developed gradually as a sequence to influenza in which purulent bronchitis has occurred, one condition passing into the next without sharp demarcation. In the second group apparent recovery from influenza has occurred, as evidenced by fall of temperature to normal. After from one to three days of normal temperature, typical lobar pneumonia with characteristic rusty sputum has developed suddenly. In the third group, lobar pneumonia has developed in cases of influenza that have been complicated by purulent bronchitis. Such cases have occasionally presented the picture of both lobar pneumonia and bronchopneumonia in the same individual.

Bacteriologic study has disclosed that all these types of pneumonia have been of pneumococcus origin in most instances. As described in greater detail below, some have been further complicated by a superimposed *Streptococcus hemolyticus* infection.

The bacteriology of the sputum early in the disease has been studied by inoculation of white mice and by direct cultures. The occurrence of pneumococci, *B. influenzae* and *Streptococcus hemolyticus* in sixty-nine cases of lobar pneumonia has been as follows:

Pneumococcus Type I, nine times (once with Type IV), or 13.1 per cent.; Type II, three times, or 4.3 per cent.; Type II atypical, fifteen times, or 21.7 per cent.; Type III, five times (once with Type IV), or 7.3 per cent; Type IV (alone), thirty-seven times, or 53.6 per cent.

Streptococcus hemolyticus has been found three times, or 4.3 per cent., in all three instances associated with pneumococcus Type IV.

B. influenzae has been found forty-three times, or 62.2 per cent., always associated with pneumococcus (Type I, six times; II, once; II atypical, ten times; III, twice, and IV, twenty-four times).

Pneumococcus Types I and II, which have a predominant part in the production of the pneumonia of civil life, have been present in a relatively small proportion of cases, whereas Type II atypical and Types III and IV are found with 82.6 per cent. of cases.

The bacteriology of the sputum in forty-three cases of bronchopneumonia was as follows:

Pneumococcus Type I, none; Type II, once, or 2.3 per cent.; Type II atypical, three times, or 7 per cent.; Type III, three times, or 7 per cent.; Type IV, thirty times, or 69.8 per cent.

Streptococcus hemolyticus has been found six times, or 14 per cent., twice with pneumococcus Type IV and four times with no pneumococci.

B. influenzae has been found thirty-eight times, or 88.4 per cent., associated with pneumococci thirty-three times (Type II, once; II atypical, three times; III, three times; IV, twenty-six times); with *Streptococcus hemolyticus* three times, and alone twice.

Here again pneumococcus Type IV has been found predominant, being present in more than two thirds of the cases. *Streptococcus hemolyticus* unassociated with pneumococci has been found in 9.3 per cent. of these cases. *B. influenzae* unaccompanied by pneumococci or hemolytic streptococci was present in two cases; but in view of observations made at necropsy, it is doubtful if this organism alone was responsible for pneumonic consolidation of the lungs.

PATHOLOGY AND BACTERIOLOGY OF PULMONARY LESIONS FOUND AT NECROPSY

The characters of the group of pneumonias that have occurred in association with the present outbreak of influenza may be defined by the pulmonary lesions found at necropsy, described in relation to the associated bacteria.

Two hundred necropsies have been performed during the outbreak of pneumonia. For the purpose of the present report it has seemed desirable to analyze seventy-nine cases which, occurring with few exceptions in sequence at the height of the outbreak, have been subjected to careful bacteriologic study. Cultures have been made from the heart's blood, from the lung and from a bronchus. When the hemolytic streptococcus has been found in the lung it has usually been demonstrable in the blood. The number of instances in which *B. influenzae* has been obtained in cultures would have been diminished more than half if cultures from the mucosa of the bronchi had not been made.

CHANGES IN THE BRONCHI

Necropsies have shown the presence of purulent bronchitis in a large proportion of those who have died with pneumonia during the course of the present epidemic of influenza. When edema of the lungs is present, the content of the small bronchi is not usually purulent, though the mucosa may be intensely injected. *B. Influenzae* can be grown with few exceptions from the mucopurulent material that wells out of the cut bronchi or from material scraped with a platinum loop from the main branches. In twenty-seven of thirty instances of purulent bronchitis from which cultures were made at necropsy, *B. influenzae* was found.

When purulent bronchitis is found, the lungs are very voluminous and preserve the shape and size of the thoracic cavity after removal; they show little tendency to collapse, even when cut. Most of the affected lungs, being from men who have come from rural districts, are pale pink and almost wholly free from coal pigment. After section a small droplet of mucopurulent fluid marks the site of each bronchus or bronchiole and doubtless explains the failure of the lung to collapse. The cyanosis of the patients with the disease is doubtless referable in part at least to the same change. The mucosa of the bronchi is intensely injected. Further evidence of severe injury to the bronchi is the frequent occurrence of a zone of hemorrhage about the smaller bronchi, particularly in the lower lobes. At times this zone of hemorrhage gives place to an encircling zone of pneumonic consolidation. Further evidence of profound injury to the bronchial wall is the dilatation that the small bronchi undergo. Bronchiectasis is most conspicuous in the basal part of the lower lobes, and is usually more advanced on the left side than on the right. Small bronchi with no cartilage in their wall may reach a diameter of 0.5 cm. More advanced bronchiectasis has been found in several necropsies performed late in the outbreak.

Among seventy-nine necropsies, selected from the 200 performed, because they have been in sequence and accompanied by careful bacteriologic study, there have been thirty-six instances of lobar pneumonia, nineteen instances of bronchopneumonia, one instance of associated lobar pneumonia and bronchopneumonia, and twenty-three instances of pneumonia with suppuration of lung tissue.

LOBAR PNEUMONIA

A group of thirty-six cases of pneumonia, taken at necropsy in sequence and studied bacteriologically, gives further knowledge of the bacteriology of the disease as it has occurred here. The results of this study have been as follows:

Pneumococcus Type I, three times; Type II, none; Type II atypical, five times; Type III, six times; Type IV, nineteen times; total, thirty-three, or 91.7 per cent.

Streptococcus hemolyticus with pneumococci, ten times; with no pneumococci, three times; total, thirteen, or 36.1 per cent.

B. influenzae thirty-one times, or 86.1 per cent.

B. influenzae has been present with few exceptions. Of pneumococci, which are frequently found in the mouths of healthy men, Type II atypical and Types III and IV are predominant, Type IV occurring in more than half of all cases, whereas Type I has been found only three times in the present series, and Type II has been found in no typical instance of lobar pneumonia. Hemolytic streptococci have been found in approximately one third of those cases of lobar pneumonia that have been unassociated with gross evidence of suppuration. It seems probable that the organism has invaded the lung late in the disease, and doubtless the micro-organism in many instances has had an important part in producing the fatal issue. This subject will be considered later when ward infection is discussed. When the hemolytic streptococcus has been unassociated with the pneumococcus it is probable that the latter has disappeared from that part of the lung from which the culture has been taken.

BRONCHOPNEUMONIA

Two varieties of bronchopneumonia have been observed repeatedly. They do not include all of the instances of bronchopneumonia that occurred: (*a*) Bronchopneumonia may cause confluent consolidation of large parts of lobes; patches of consolidation, accurately limited to the secondary lobules of the lungs, occur. The larger patches of consolidation are sharply limited by lobule boundaries so that the consolidated tissue on the cut section projects conspicuously above the air-containing lung substance. Even within the large consolidated areas, which are blackish red, red or grayish red and finely granular, the lobules are well defined; but there is no thickening of the interstitial tissue. Two instances of pneumonia due to pneumococcus Type II were of this character. In three other cases the lesion was caused by pneumococcus Type IV. (*b*) This confluent lobular consolidation is not the predominant variety, and disseminated nodules or patches of reddish, gray or yellow consolidation are more commonly seen. The bacteriology of nineteen cases of bronchopneumonia has been as follows:

Pneumococcus Type I, none; Type II, twice; Type II atypical, none; Type III, none; Type IV, ten times; total, twelve, or 70.6 per cent.

Streptococcus hemolyticus with pneumococci, seven times; with no pneumococci, five times; total, twelve, or 70.6 per cent.

B. influenzae, seventeen times, or 89.4 per cent.

Pneumococci doubtless have a predominant part in the production of the disease, and hemolytic streptococci act as secondary invaders. Nevertheless it is possible that hemolytic streptococci in the presence of influenza may independently invade the lung and produce bronchopneumonia without suppuration.

SUPPURATIVE PNEUMONIA

Suppuration has occurred in more than one fourth of the cases that have been examined postmortem. Three varieties of suppurative lesion have been found.

(*a*) Localized abscess formation within a patch of pneumonic consolidation. A patch of consolidation about one abscess is occasionally the only evidence of pneumonia, but more frequently there are multiple patches of bronchopneumonia. The abscess or abscesses are usually situated immediately below the pleura, often separated from the cavity by remains of the membrane no thicker than tissue paper, and the cavity is the site of purulent pleurisy with effusion varying from several hundred up to 1,700 c.c. In all but one of eleven cases of abscess with bronchopneumonia, hemolytic streptococci were found both in the blood of the heart and in the affected lung. In the one exceptional case, pneumococcus Type IV was obtained from the blood; no growth was obtained on the plate inoculated from the lung, and hemolytic streptococci with *B. influenzae* were found in the bronchus. *B. influenzae* was found in the bronchi (six) or in the lung (two) in all but three of these eleven cases. There can be no doubt that the suppurative process due to hemolytic streptococci was in some instances superimposed on pneumonia caused by pneumococci. In one instance, associated pneumococcus Type II was present in blood, lungs and bronchus; in one instance, pneumococcus Type IV was present in blood and bronchus. Of less significance has been the demonstration of associated pneumococci, Type II atypical or Type IV, in the bronchi or lungs (three instances).

(*b*) Pneumonia with suppuration of the interstitial tissue. In association with bronchopneumonia (three times), with typical lobar pneumonia (twice) or with all defined patches of consolidation (three times), probably best classified as bronchopneumonia, suppuration of the interstitial tissue of the lung has occurred eight times among our cases with completed bacteriologic examination. The interstitial septums appear as conspicuous yellow lines from which purulent fluid may be scraped. The septums are usually swollen to a thickness of about 1 or 2 mm., but wide lines of suppuration 0.5 cm. across are seen. Edematous swelling of septums outside of the consolidated tissue is not infrequently found. These suppurating septums extend up to the pleura, and the overlying lymphatics are often widely distended with fluid. Purulent pleurisy usually with copious effusion up to 1,900 c.c. has been found. In seven of these eight cases, hemolytic streptococci were found both in the heart's blood and in the affected lung. In one instance of lobar pneumonia with interstitial suppuration, we found pneumococcus Type IV with no hemolytic streptococci in the heart's blood and lungs. By unfortunate error, no culture from the affected lung is recorded. The relation of the lesion to associated infection with pneumococci is important. Pneumococcus Type II was found in one instance associated with hemolytic streptococci in the heart's blood, lung and bronchus. In one instance, pneumococcus Type II atypical with *B. influenzae* was found in the sputum during life unassociated with hemolytic streptococci, whereas three days later pneumococci were not demonstrable in the lungs or bronchi, and hemolytic streptococci were found in blood, lungs and bronchus. In another case, pneumococcus Type IV and hemolytic streptococci were found in the sputum during life, whereas after death five days later pneumococci had apparently disappeared and hemolytic streptococci were found in the blood and the bronchus, with *B. influenzae* in the latter situation.

(*c*) Multiple abscesses clustered about bronchi. In four instances in the group of cases under consideration, suppuration has occurred within bronchopneumonic patches clustered about a medium sized bronchus. These abscess cavities in communication with the bronchus are several millimeters up to 0.5 cm. in diameter, and are surrounded by gray, consolidated tissue. The patch of consolidation studded with abscesses may be scarcely more than 5 cm. across, but a much larger area may be involved. There has been no empyema nor plural effusion in these cases.

The bacteriology of the four cases cited has been as follows:

Necropsy 280.—Hemolytic streptococci were found in the heart's blood, in consolidated lung tissue and in the bronchus. In the bronchus were found *B. influenzae* and a few staphylococci. Culture from the abscess was contaminated.

Necropsy 322.—The blood was sterile. *Staphylococcus aureus* was obtained from consolidated lung; *Staphylococcus aureus* and pneumococcus Type III were obtained from the abscess.

Necropsy 329.—The blood was sterile. *Staphylococcus aureus* and pneumococcus Type IV were obtained from the abscess; *B. influenzae*, *Staphylococcus aureus* and pneumococcus Type IV from the bronchus.

Necropsy 333.—The blood contained pneumococcus Type II atypical; *Staphylococcus aureus* and pneumococcus Type II atypical were obtained from the abscess; *Streptococcus hemolyticus* from the lung on the opposite side; *Staphylococcus aureus*, *B. influenzae* and a few hemolytic streptococci from the bronchus.

The foregoing observations indicate that *Staphylococcus aureus* may be engrafted on a pneumococcus pneumonia and cause suppuration in clustered foci, unaccompanied by empyema.

WARD INFECTION

Transmission of Streptococcus Pneumonia.—The fatal effect of the necessary overcrowding of this hospital is well shown by a comparison of the death rate from pneumonia in wards, on the one hand, which had long been organized for the care of patients with pneumonia, and in wards, on the other hand, which were opened for patients with pneumonia and immediately overfilled at a time when the hospital was overwhelmed by the epidemic of influenza.

Ward 3 was provided with cubicles and conducted by medical officers, nurses and enlisted corps men accustomed to the care of patients with pneumonia. The figures in Table 4 show the number of patients in the ward each day from September 6 to October 5, the number of patients admitted each day and the number of deaths among patients admitted on the corresponding day. The first period of ten days immediately preceded the present outbreak of pneumonia (Table 1). During the second period of ten days the incidence of pneumonia gradually increased, and during the third period maintained its maximum.

* In this and in the following three tables, these figures do *not* indicate the number of deaths on the *corresponding* dates but represent deaths which eventually occurred among patients admitted on these dates.

It is noteworthy that the death rate from pneumonia among those admitted during the first ten days was 27.2 per cent. at a time when the ward contained from fifteen to twenty-one patients. It increased during the second ten days, when the ward contained from twenty-five to sixty patients, to 30.7 per cent. With further increase of the ward population to from fifty-five to sixty-one, the death rate among those admitted during this period rose to 34.7 per cent. If the case of pneumonia due to infection with hemolytic streptococcus which occurred in each of the second and third periods be omitted, the figures for the three periods will be, respectively, 27.2, 28.8 and 30.4 per cent. In spite of the overcrowding of the ward, the introduction of two cases of streptococcus pneumonia under the favorable conditions existing in the ward did not cause an outbreak of the infection.

Ward 8 had long been used for the care of colored patients with pneumonia. Cubicles were in use and precautions were taken against the spread of infection. During the period from September 1 to September 20, all new patients with pneumonia admitted were treated on the porch of the ward, the remaining population of the ward being largely convalescents who were placed inside. During the period from September 21 to October 5, when the influenza epidemic was at its height, the ward rapidly filled with active cases of pneumonia and became distinctly crowded. Nevertheless, no outbreak of secondary infection with the hemolytic streptococcus occurred.

Ward 2 was opened, September 28, during the period in which twenty new wards for pneumonia were organized. From September 26 to October 1, the cubicle system was not in use, the ward was crowded, organization was imperfect, and few precautions were taken to prevent the transfer of infection from one patient to another. October 2, the cubicle system was introduced, and strict and efficient precautions for the prevention of infection were instituted.

Among patients admitted between September 26 and 28 there was a ward epidemic of streptococcus pneumonia. Nine of the fifty-seven patients admitted to the ward between September 26 and October 1 were shown by examination of the sputum to have pneumococcus pneumonia free from hemolytic streptococci. All died, seven with infection by the hemolytic streptococcus, one with what was presumably an acquired infection with pneumococcus Type III (pneumococcus Type IV was found in the sputum on admission), and one with undetermined cause (*no* necropsy was held). The sputum of no other patients in this ward was examined on admission.

September 29 (the beginning of the second period), the porch of the ward was put into use, and of twelve patients admitted on this date eleven were put on the porch. Of these eleven patients, eight recovered and three died, of whom two were transferred to beds within the ward on the day after admission. The use of the porch doubtless explains the diminished mortality of this period.

From October 5 to 7 the ward was closed to further admissions, save six patients transferred from Ward 1 seriously ill; of these all died. After October 7, admissions were limited to patients with pneumonia in whom throat swab had demonstrated *Streptococcus hemolyticus.*

Ward 1 was opened, September 24. During the period from September 24 to October 1, the cubicle system was not in use and there were few precautions to prevent transmission of infection. October 2, the cubicle system was installed, and somewhat insufficient precautions against the spread of contagion were instituted. Beginning October 6, the ward was closed to further admission. Table 7 is divided into two periods, the first ending September 29, because on September 29 and 30 four patients infected with hemolytic streptococci were admitted to the ward. Deaths that occurred (with no reference to date of admission) prior to September 30 were all due to pneumococcus with one exception, namely, a patient entering the ward on September 26 and dying several hours later.

Hemolytic streptococci introduced into Ward 1 containing patients suffering with pneumonia due, as our experience here has shown, to pneumococci, has produced an epidemic of secondary infection with streptococci. Though the ward was evidently in great danger of infection from September 24 to 29, as the result of unfavorable conditions, none appears to have occurred; but with the introduction of the microorganism, September 29 and 30, widespread dissemination of fatal infection was immediate.

The occurrence of ward infection is well shown by the bacteriologic examination of the heart's blood and lungs at necropsy. Up to October 6, necropsies were performed on nearly all patients dying with pneumonia. The results of bacteriologic examination at necropsy of patients dying in pneumonia wards is given in Table 8.

The figures demonstrate that routine necropsies with bacteriologic examination of the blood and lungs of every patient that has died with pneumonia furnishes a certain means of recognizing the occurrence of ward infection with hemolytic streptococci. This means of checking the results of bacteriologic examination of the throat and sputum should never be neglected. The recognition of suppurative pneumonia, even when no cultures are made at necropsy, will indicate that pulmonary infection with hemolytic streptococci exists. It is obviously essential to separate pneumonia patients harboring hemolytic streptococci in the mouth from those that are free from this organism; but the existence of hemolytic streptococci in the mouth of patients with pneumonia is not conclusive evidence that the lung has been invaded.

These necropsies, with the accompanying bacteriologic studies, gave us the first conclusive evidence that the pneumonia in this hospital following influenza was subject to secondary invasion with hemolytic streptococci. They showed that Ward 3 had been maintained almost free from pyogenic infection; they forced the conviction that all patients who might subsequently be admitted to Ward 2 would with relatively few exceptions die with it. The ward was closed. The grave danger to patients entering Ward 1 was recognized, and this ward also was closed to subsequent admissions. The throats of all the 900 patients in the hospital were swabbed as rapidly as accessible facilities permitted, and patients harboring hemolytic streptococci were separated from those that were free from the micro-organism.

* With the exceptions of Wards 1, 2, 3 and 8, these wards had been opened less than one week.

† One of these cases of streptococcus pneumonia was the wardmaster of Ward 2, whose illness began, October 1, during the period of severe infection of this ward.

Transmission of Pneumococci.—The foregoing observations have demonstrated that streptococcus pneumonia may spread by contagion throughout an entire ward. Subsequent observations have demonstrated that pneumococci may be transmitted in the same way. Opportunity to obtain this evidence has been favored by the predominance of Types IV, III and II atypical among the pneumonias occurring here. Among cases of pneumonia of which the type has been determined between September 6 and October 1, only six instances of Type II pneumonia were found. Two of these cases occurred in Ward 3, and there is evidence that the disease was transmitted from these patients to three others in adjacent beds.

Infection with pneumococcus Type II occurred in a patient, Private P., recovering from pneumonia caused by pneumococcus Type IV. This infection with pneumococcus Type II was apparently acquired from a patient, Private Sw., occupying an adjacent bed.

Private Sw. was admitted to Ward 3 and placed in Bed 3, September 16, one day after the onset of pneumonia. Pneumococcus Type II was found in his sputum. His crisis occurred, September 21, on the sixth day of his illness. At the time Sw. was admitted, Private P. occupied Bed 5, separated by one bed from Sw.; he had been admitted, September 9, and had bronchopneumonia with signs of consolidation in the left lower lobe. Pneumococcus Type IV was found in his sputum. A crisis occurred, September 14, and the temperature remained normal until September 24, save for a sharp rise, September 20 to 21, lasting eighteen hours. A second attack of pneumonia began, September 24, and death occurred, September 30. Necropsy disclosed the presence of lobar pneumonia with gray hepatization of the greater part of the right lower lobe and of the left lung. Pneumococcus Type II was found in the heart's blood and in the lung, and with *B. influenzae* in the right bronchus. Private P. had the opportunity to acquire his second infection from Private Sw.

TABLE 9.—REPORT OF TWO CASES OF PNEUMONIA

Name	Admitted	Bed Occupied	Pneumococcus in Sputum on Admission	Course of Disease	Pneumococcus Found at Necropsy
Private Sw.	Sept. 16	3	Type II	Crisis, Sept. 21	
Private P.	Sept. 9	5	Type IV	Crisis, Sept. 14; second attack of pneumonia, Sept. 24; death, Sept. 30; lobar pneumonia	Type II

Infection with pneumococcus Type II occurred in two patients apparently recovering from other types of infection, in one instance caused by pneumococcus Type II atypical, and in another by Type IV. In both instances pneumococcus Type II has apparently been acquired from a third patient occupying an adjacent bed.

Private Sm. was admitted with pneumonia to Ward 3 and placed in Bed 26, September 18. Pneumococcus Type II was found in the sputum. The patient died, September 27, with bronchopneumonia. There were scattered patches of lobular consolidation and diffuse consolidation of the greater part of the right upper lobe. Pneumococcus Type II was found in the heart's blood.

TABLE 10.—REPORT OF THREE CASES OF PNEUMONIA

Name	Admitted	Bed Occupied	Pneumococcus in Sputum on Admission	Course of Disease	Pneumococcus Found at Necropsy
Private Sm.	Sept. 18	26	Type II	Died, Sept. 27; bronchopneumonia	Type II
Private T.	Sept. 17	28	Atypical II	Crisis, Sept. 19; temperature normal until Sept. 21, when it rose to 104.4; death, Sept. 29; lobar pneumonia	Type II
Private L.	Sept. 16	30	Type IV	Some improvement occurred, Sept. 24 and 25, but temperature did not become normal; death, Sept. 30; bronchopneumonia	Type II

Private T. had been admitted to Ward 3, September 17, with a diagnosis of bronchopneumonia and signs of consolidation in the right lower lobe. Pneumococcus Type II atypical was found in the sputum. Crisis occurred, September 19, and the temperature was normal until 8 p. m., September 21, when there was a sudden rise to 104.4; death occurred, September 29. At necropsy there was firm hepatization with yellow color and characters of lobar pneumonia at posterior parts of both lower lobes; but throughout the remainder of the lungs there were small scattered patches of bronchopneumonic consolidation. Pneumococcus Type II was obtained from the heart's blood and lungs; *B. influenzae* was found in the consolidated part of the lung and in the right bronchus. At the time T. developed his second attack of pneumonia he occupied Bed 28, separated by one bed from that occupied by Sm., admitted with pneumonia caused by pneumococcus Type II.

Private L. was admitted, September 17, with lobar pneumonia and signs of consolidation in the left lower lobe. Pneumococcus Type IV was isolated from the sputum. There was some improvement, September 24 and 25, but the temperature never returned to normal and his condition was worse, September 26, when he developed signs of pericarditis. He died, September 30. The left upper lobe was consolidated, rather flabby and had a homogeneous, fleshy appearance. In other parts of the lung there were small scattered patches of bronchopneumonic consolidation and diffuse purulent bronchitis. Pneumococcus Type II with *B. influenzae* was isolated from the right lung, alone from the left lung, and with *B. inflenzae* and *Streptococcus viridans* from the right bronchus. L., from whose sputum on admission pneumococcus Type IV was obtained, occupied Bed 30, separated by one bed from T. and by three beds from Sm., both of whom suffered with Type II pneumonia.

TABLE 11.—REPORT OF FIVE CASES OF PNEUMONIA

Name	Bed Occupied	Pneumococcus in Sputum on Admission	Course of Disease	Pneumococcus Found at Necropsy
Pg.	48	Atypical II	Returned to duty, Oct. 8	
J.	49	Atypical II	Died, October 4	Atypical II
Lw.	50	I	Crisis; recurrence; died, October 8	Atypical II
Sc.	51	Atypical II	Returned to duty, Oct. 25	
C.	53	Atypical II	Died, September 25	Atypical II

The group of cases that has been described is especially significant because these are the only cases of Type II pneumonia save one recognized before October 1. Private P., in Bed 5, doubtless acquired his infection with pneumococcus Type II from Sw. in Bed 3; Private T., in Bed 28, and L. in Bed 30, from Sm. in Bed 26. It is doubtful if the infections of Sw. and Sm. have any relation to each other.

An instance of the transmission of pneumococcus Type II atypical occurred in Ward 8. Privates Sc. and L. were admitted to the ward, September 21, and assigned to Beds 51 and 50. Privates Pg., J. and C. were admitted to the ward, September 22, and given Beds 48, 49 and 53, respectively. The history of these patients is given briefly in Table 11.

Private Lw., who became ill one day before his admission, suffered with pneumonia caused by pneumococcus Type I, demonstrated by examination of the sputum on the day following admission. *B. influenzae* was found. He was in bed adjacent to J. with Type II atypical, who remained beside him until October 4, and one bed distant from Pg., with Type II atypical, who remained in Bed 48 until October 4, when he was transferred to another part of the ward. On the other side of Lw. was Sc., with Type II atypical, who remained in Bed 51 until October 9, when he was moved to another part of the ward. C., with Type II atypical in Bed 53 died, September 25. Lw. had frank lobar pneumonia with consolidation of the right lower lobe, and crisis occurred, Sept 29, that is, on the ninth day of illness. The temperature remained normal until October 2, when there was sudden elevation of temperature to 104.2. Death occurred, October 8. Necropsy disclosed lobar pneumonia with gray hepatization of the right upper lobe. The heart's blood and the right lung contained pneumococcus Type II atypical in pure culture. Lw. doubtless acquired his second infection from the group of patients with the same micro-organism surrounding him.

There have been two instances in which, after one type of organism, namely, pneumococcus Type IV, has been found in the sputum by inoculation of white mice and subsequent identification of the pneumococcus, a different type has been demonstrated in the blood or lung at necropsy. Private G. was admitted to Ward 2, September 27, and pneumococcus Type IV and *B. influenzae* were found in his sputum. He died, October 2. There was acute lobar pneumonia with suppuration of the interstitial tissue of the lung and empyema. The heart's blood, lung and bronchus contained pneumococcus Type II; *B. influenzae* was found in the bronchus. Private Sp. was admitted to Ward 2, September 25. Pneumococcus Type IV was obtained from the sputum. He died, October 3; there was acute bronchopneumonia with multiple clustered foci of suppuration, and pneumococcus Type III and *Staphylococcus aureus* were found in the lung. Even should we assume that pneumococcus Type III in this instance descended into the lungs from the patient's mouth, the case indicates that reinfection of a pneumonic lung with pneumococci is possible.

The foregoing data show that pneumonia of one type does not establish any trustworthy immunity from other types of pneumococci. Patients with one type of pneumococci, notably in the examples cited of Type II, may infect with fatal result patients suffering with or recovering from other types of pneumonic infection. In the absence of streptococcus pneumonia it is essential to maintain in a pneumonia ward precautions that will prevent transmission of infection from one patient to another.

SUMMARY

During the epidemic of influenza that has been studied, one fourth of those in the camp suffered with the disease; 12.1 per cent. of those attacked with influenza developed pneumonia, and 3.8 per cent. died.

Influenza tended to select newly drafted men, and was twice as common in men who had been in the camp less than one month as in those of longer residence. The incidence of pneumonia among newly drafted men was even higher; 62 per cent. of the cases of influenza were in men in camp less than one month; 67.5 per cent. of cases of pneumonia were in men in camp less than a month.

B. influenzae can be demonstrated often in immense number in the nose, throat, or sputum of every patient with influenza, and with few, if any, exceptions in the bronchi of those who have had the purulent bronchitis that follows influenza. The same organism can be found in the throats of some healthy individuals.

Pneumonia follows influenza because the disease renders the air passages susceptible to the invasion of a variety of micro-organisms, among which those commonly found are pneumococci, hemolytic streptococci, and staphylococci.

The profound injury to the air passages produced by influenza is shown by the consequent purulent bronchitis and bronchiolitis preventing collapse of the lung after removal at necropsy, by peribronchial hemorrhage, by dilatation of small bronchi, and ultimately by the formation of multiple bronchiectatic cavities.

Both lobar pneumonia and bronchopneumonia follow influenza, but the disease is somewhat less frequently lobar pneumonia than bronchopneumonia.

Lobar pneumonia following influenza at Camp Pike has been caused in most instances by pneumococci that occur in the mouths of healthy men, namely, by Type IV, 53.6 per cent.; Type III, 7.3 per cent, or Type II atypical, 21.7 per cent., whereas it is seldom caused by Type I, 13.1 per cent., or Type II, 4.3 per cent. Bronchopneumonia has shown similar preponderance of Type IV, 69.8 per cent. It seems probable that Types I and II are much less abundantly distributed among the troops of this camp than in those civil communities where most previous observations have been made.

Among the necropsies that have been performed here, typical lobar pneumonia occurred in about one half of the cases, bronchopneumonia alone in somewhat less than a fourth, and suppurative pneumonia usually superimposed on bronchopneumonia in slightly more than a fourth of the cases.

Three types of suppurative pneumonia occur: (*a*) Localized abscess formation within a patch of pneumonic consolidation, usually in immediate contact with the pleura and accompanied by empyema. Hemolytic streptococci are found at necropsy in the lung, in the bronchi, in the inflamed pleural cavity, and in the heart's blood. (*b*) Suppuration of the interstitial tissue of the lung superimposed on bronchopneumonia or occasionally on lobar pneumonia. The suppurative process extends up to the pleural surface, and there is empyema. Hemolytic streptococci are found in the situations named above (under *a*). (*c*) Multiple foci of suppuration clustered about a medium sized bronchus. Empyema has not been found. *Staphylococcus aureus* has been present in the lesion.

The sequence of events that occurs in many cases of influenza is as follows: *B. influenzae* descends into the bronchi; pneumococci (in this camp usually Type IV) invade the inflamed bronchi, enter the lung, and produce either lobar pneumonia or bronchopneumonia. Hemolytic streptococci may descend and infect the pneumonic lung. It is not improbable that hemolytic streptococci may invade the bronchi previously infected with *B. influenzae* and cause bronchopneumonia in the absence of pneumococci.

When hemolytic streptococci invade the lung either with or without preceding pneumococcus infection, there may be no suppuration of the lung. It is probable that death has occurred before there is opportunity for the formation of abscesses. *Streptococcus hemolyticus* may pass through a pneumonic lung and appear in the heart's blood although there has been no suppuration. It is not improbable that it may pass through the lung and produce empyema, the lung remaining free from actual suppuration. Lobar pneumonia appears to resist suppuration more effectively than bronchopneumonia; but fatal streptococcus infection is common with both.

Infection with hemolytic streptococci may spread as an epidemic through the pneumonia wards of a hospital. A single patient with streptococcus pneumonia is a source of grave danger to every patient in the same ward. Superimposed infection with hemolytic streptococci increases the mortality of pneumonia so that it may reach from 50 to 100 per cent. of all patients with pneumonia.

Streptococcus pneumonia is introduced into a ward by the admission of a patient with the disease, or doubtless by a patient or attendant harboring hemolytic streptococci in the throat. Transmission of infection is favored by overcrowding, by failure to recognize the disease, by imperfect separation of patients by cubicles and other means, and by imperfect aseptic technic of medical officers, nurses and attendants.

Patients suffering with or recovering from pneumonia caused by one type of pneumococcus may be reinfected with another type of pneumococcus, and fatal pneumonia may result. General conditions that facilitate the transmission of streptococci outlined above favor the occurrence of reinfection with pneumococci.

The history of influenza and pneumonia at Camp Funston[1] indicates that epidemics of influenza and consequent pneumonia will follow the present epidemics of influenza when new drafts from isolated rural districts are brought into camps that have been attacked by the disease. There seems little reason to doubt that the incidence of pneumonia and the death rate of that which occurs might be greatly diminished by preventing all overcrowding of new recruits in barracks and by providing hospital facilities in considerable excess of the routine demand.

Hospital epidemics of streptococcus pneumonia will be prevented when medical officers have that dread of the disease—comparable to our dread of puerperal fever—which is inevitable when its characters are accurately understood. To promote a more widespread recognition of its nature, the use of a readily understood designation, such as streptococcus pneumonia, should be encouraged.

Streptococcus pneumonia is a preventable disease: (*a*) The technic of a pneumonia ward must be comparable to that of the best maternity hospitals, with added precautions to prevent patients from disseminating by coughing or other means ejected material containing streptococci, pneumococci or other micro-organisms. (*b*) The throats of all patients with pneumonia should be swabbed before they are admitted to a ward set aside for the treatment of pneumonia in order to determine if they harbor hemolytic streptococci (demonstration of hemolytic streptococcus in the throat does not prove that the lung is invaded). (*c*) Patients with pneumonia harboring hemolytic streptococci should be kept in a separate ward into which none free from these micro-organisms are admitted. (*d*) When streptococcus pneumonia makes its appearance in a pneumonia ward, the ward should be closed to further admissions. It would doubtless be closed if diphtheria or scarlet fever had appeared and the danger from streptococcus pneumonia is greater. (*e*) Necropsies should be performed on every patient dying with pneumonia, and appropriate bacteriologic cultures should be made from the heart's blood and from the lungs as a means of determining the presence or absence of streptococcus pneumonia and to serve as an index of the efficiency of the precautions in force.

FEIGNED AMNESIA AS A DEFENSE REACTION *

GEORGE E. PRICE, M.D. (Philadelphia)
Major, M. C., U. S. Army; Consultant in Neuropsychiatry, District of Paris
and
WILLIAM B. TERHUNE, M.D. (New Orleans)
First Lieutenant, M. C., U. S. Army
A. E. F., France

The examination of soldiers under arrest at the office of the provost marshal of Paris has revealed a number of individuals feigning loss of memory for the purpose of escaping punishment. This form of malingering was employed as a last resort when the culprits were without other excuse. The charge under which they were held was in every instance that of being absent from their unit without permission, and in no case was amnesia alleged to escape duty at the front.

It was interesting to note that all of these men were native Americans. None presented any evidence of mental deficiency, the majority being somewhat above the average of intelligence. One was a captain, two were first lieutenants, and the others were privates. Such civil occupations were represented as machinist, newspaper reporter, court stenographer, telegrapher and student.

The condition observed was characterized by an alleged absolute blank in the continuity of memory, corresponding to the period of time during which the individual thought it necessary to be excused from his actions. This period varied according to the astuteness of the soldier. Some deemed it wise to remember nothing of their past life, others limited it to incidents occurring during the past few years, while the majority claimed an amnesia corresponding to the period of their misdemeanor.

A typical statement would be somewhat like this: "The military police picked me up in the street because I had no papers. I do not know how I got to Paris, how long I have been here, or what I have done. The first thing that I remember was this morning."

REPORT OF CASES

The subjoined reports are abstracted from the records:

Case 1.—A private stated that he had arrived in Paris two nights before, he did not know how. He went to a military policeman and gave himself up. He did not know what his organization was or when he enlisted, but he was not drafted. His home was in California, he did not know where. He was not married. He came to France in cold weather, he did not know when. He landed in France, he did not know at what port. He did not know the name of the boat he crossed on; it had one smokestack. He thought he had been a teamster in France. He did not know what he did in civil life. He had been at the front.

The patient denied memory for recent and past events. His attention was good. There was no disorientation nor confusion. He answered questions promptly. He was able to answer problems involving multiplication and division promptly and accurately.

Physical examination was negative.

Case 2.—A private was not sure of his name. He found an envelop in his pocket and he imagined it was addressed to him. This letter was from California. He said that he thought California was in the United States, but he could not say where the United States was. He did not know where his home was or anything about his people. He supposed he had parents because everybody must have them. He did not think that he was married. He felt all right. He did not know his age, length of service in the Army, or length of service in France. He said that up to the time he found himself in the subway in Paris, Oct. 4, 1918, everything was a blank. This recovery of "consciousness," he stated, was due to a fall in the subway. He remembered all events since then perfectly. After he fell in the subway he went to his hotel and the next day reported to the provost marshal.

---

* From American Red Cross Military Hospital No. 1.

The patient was well oriented, his attention was excellent, he was well informed about Paris, and he appeared very intelligent. He seemed to realize that his story was very weak.

Case 3.—A captain was charged with having been absent without leave for six weeks; with having been drunk and disorderly; of being in debt to a hotel for 1,500 francs; of brutalizing a woman who was registered at a hotel as his wife; of resisting arrest, and of attempting to break arrest. His identity card said that he was a first lieutenant, but he wore a captain's insignia and probably was a captain.

The patient had no memory of leaving his organization, and did not remember anything that had happened since. The patient stated that he did not know what month it was or why he was under arrest. He answered all questions readily that could not be used against him, but did not remember anything that he did not wish to remember. His attention was excellent, his train of thought well connected, and his intelligence keen.

COMMENT

It was not difficult in the majority of instances to expose the malingering by noting the inconsistency existing in the patient's statements. One man stated that he did not know the name of the boat on which he crossed the ocean, but later he said the boat had been torpedoed recently. When asked how he knew this he said he had read it in the papers. Another individual said that for the past few weeks he had been unable to recall any facts connected with his past life, including the name and address of his relatives. This man when questioned as to when he had last written home replied that he had a nurse write his sister while he was in a hospital. This was written at a time during which he had just claimed that he could not remember the address of his relatives.

The Café de la Paix seemed to hold a peculiar attraction for many of the patients brought up for examination. To such an extent was this true that it made a bright spot in a long day of routine examinations to have a soldier solemnly affirm that the first thing that he remembered for weeks was the military police grasping him by the shoulder in the Café de la Paix. The explanation of this is simple. This popular resort, dear to the heart of the American soldier in France, is situated at the intersection of the grand boulevards of Paris and is therefore the most central point in the city. Around this place the military police drew their net in the search for men absent without leave, and consequently here many of the men examined were arrested.

The mechanism of this reaction is easily understood, provided one has some knowledge of the psychology of the American soldier. It is so easily explained that even the psychanalyst would find it difficult to attribute the condition to repressed sexual complexes. A soldier, tiring of his routine life, leaves his organization without permission, in search of a few days' recreation. Many of them do this without being detected; but some are not so fortunate, and find themselves under arrest and called on to explain their actions. They know that they have no excuse; and having recently read about men losing their memory from "shell shock," they quickly seize on that as a means of escape, feeling that the less they say in their present predicament the better it will be.

The soldier realizes that when he returns home his family may require from him an explanation for his arrest while in the army, and what better excuse can he have than that mysterious and strange malady of shell shock, so well known to his people from the description in the popular literature? This explanation will raise him from the depths of disgrace to a hero's pedestal.

Usually there was a history of only one attack of amnesia; but one man, who was not an epileptic, gave a history of four such gaps in his memory, each developing at a most convenient time and disappearing after he was extricated from his difficulty.

Feigned amnesia is important not so much of itself but because of the possibility of its being confused by the uninitiated with certain forms of true amnesia, such as those seen in hysteria and certain confusional states.

We have seen true amnesia occurring in soldiers in hysteria, psychasthenia, mental confusion resulting from exhaustion, toxic states as the result of alcoholism and other drugs, epilepsy, various other psychoses, following cerebral concussion, and organic brain injuries.

The chief conditions that must be differentiated from feigned amnesia are hysteria and simple confusion from exhaustion. We have not seen hysterical amnesia without other manifestations of hysteria. The men feigning amnesia were alert and keen, and their attention was excellent, in marked contrast to the mental state of the hysteric. When the confusion following exhaustion is marked, there is no question of the diagnosis; but frequently the confusion is slight, and these cases are often difficult to differentiate from feigned amnesia. A careful study of the patient's story of exhaustion, together with his irritability, slight disorientation, and other symptoms of mental and physical exhaustion, form a basis for the differentiation.

A GENUINE CASE

The subjoined report is abstracted from the record of examination of a first lieutenant who was found to be suffering from simple confusion following exhaustion. It is quoted to show the difference between this condition and feigned amnesia:

History.—The patient left the front for Beauvais on twenty-four hours' leave after having been on active service, continuously under shell fire, for two months. He remembered going into a wine shop as soon as he reached Beauvais, and then remembered getting into a large automobile with other officers. He next turned up at A. R. C. M. H. No. 1, having been brought in with some wounded soldiers. He was sent from this hospital to U. S. Camp Hospital No. 4, where he remained for a few days; then he went with some other officers to the Elysée Palace to get his pay check. In some way he became separated from the other officers and disappeared for about a week, to be returned later to U. S. Army Camp Hospital No. 4. In the interval he had been wandering about the front trying to find his old command and finally had been sent to the hospital by a French officer, accompanied by a French corporal. He was then investigated by the provost marshal in response to a request from his commanding officer, who reported that he was absent without permission.

Examination.—There was amnesia of events between his arrival in Beauvais until he found himself in U. S. Army

Camp Hospital No. 4. Memory for events during this time was vague, being similar to that of a dream state. He was irritable and easily startled by sudden and unexpected noise. He was slightly depressed and inclined to be lacrimose. He had a slightly furtive attitude. His judgment was not good. His train of thought was not well connected. There was no paranoid trend, no hallucinations nor delusions. He did not know who his physician was at the hospital. There were tremor of the fingers and tongue, slight photophobia, and conjuctival injection. Other physical findings were negative.

Extract from Conversation.—"Damned if I know what I did in Paris. Those fellows (provost marshal) know, I suppose."

"How did you get your pay check?" "By God, that is why I came to Paris; you said something there."

"My ideas are hazy. The last two or three weeks I was up there I was not all right, I would raise hell with a man for nothing."

CONCLUSIONS

1. Feigned amnesia has assumed a place of importance in psychiatry because of the tendency of many examiners to classify it as amnesia due to hysteria.

2. The condition is a defense reaction to escape punishment. It is not unfamiliar to civil practitioners engaged in medicolegal work.

3. Amnesia, when alleged in industrial circles, may be of similar feigned character, for the purpose of gain. It is encountered in accident litigation, being in this case due to the expectation of compensation.

4. The dissemination of misinformation about "war neuroses" under the title of "shell shock" is to be regretted. The popular idea regarding this condition is erroneous, owing to the premature and inaccurate descriptions published. This has in turn been responsible for a larger incidence of the disease in the army than is justified, and has also enabled men to seize on it as an excuse for misdemeanors.

A NEW NEMATODE INFECTION OF MAN

CHARLES A. KOFOID (BERKELEY, CALIF.)
Major, Sanitary Corps, U. S. Army
AND
A. W. WHITE, M.D. (PORTLAND, MAINE)
Major, M. C., U. S. Army
NEW YORK

In the course of the hookworm survey of increments of troops arriving at Camp Travis, Texas, and of various military units of the Southern Department (Texas, Oklahoma, New Mexico and Arizona) by the Laboratory Car *Metchnikoff*, a nematode ovum, apparently undescribed, has been found in 429 cases among approximately 140,000 soldiers examined. This ovum is the largest ovum of intestinal worms encountered in human stools. Its dimensions average 95 by 40.2 microns, with a ratio of length to diameter of 2.4:1. It is extraordinarily variable in size and proportions, its length ranging from 68 to 133 microns and its diameter from 33 to 43. The ova of *Necator americanus* in our material measured 69 (from 63 to 72) by 38 (from 35 to 43) microns. These are averages of twenty measurements in both species.

This new ovum is characterized by two marked diagnostic features that clearly distinguish it from other nematode ova of man: The first is a broad concavity on one face usually concealed by the position of the ovum when floating on brine, so that it appears only as a flattening on that face. The other feature is the presence of two highly refractive hyaline, bluish green globules flattened asymmetrically at the two poles of the embryo. They are sometimes combined in one large lateral or polar globule, or are broken up into smaller moieties. They are dispersed as development proceeds. The larva partakes of the color of the globules. The egg is a broadly rounded asymmetrical ellipsoid, with clearly defined double contoured eggshell similar to that of the hookworm. In some instances the faintest tinge of brown can be detected in optical sections of the shell. There is sometimes a small irregularity in the contour toward one end on the concave surface suggestive of an operculum.

The eggs at oviposition in fresh stools are in the late morula to coiled larval stages, the latter often in elongated, slender ova. Attempts to hatch the egg in water, boneblack, at air temperatures, in the incubator at blood heat and below, and in human gastric and duodenal fluids have all failed. Cobb[1] was unable to hatch the ova of *Oxyuris vermicularis* in artificial digestive fluids, although he did succeed in securing developing larvae from ova passed through the human digestive tract in a suction capsule. Spasmodic movements in the coiled larvae in the shell have been noted.

The infections are most of them light, only a single ovum being found in many cases. The maximum number detected on one slide by the Kofoid-Barber brine-loop method was twenty-four.

The affinities of the ovum are suggested by its size, proportions and contour. On a partial survey of the literature of nematodes, human and of other mammals, no reference has been found to such hyaline globules. Minute globules of similar physical characteristics appear in some ova of *Oxyuris vermicularis*. The flattening on one face is a family characteristic of the ova of *Oxyuridae*. The size and proportions of this ovum fit about midway into those of the species of *Oxyuris* found in rodents, such as rabbits, rats and mice. We therefore tentatively assign this species to *Oxyuris* as *Oxyuris incognita* sp. nov., pending the discovery of the adult stage. There is a possibility of its being a *Trichostrongylus*, but the ova of the known species of that genus are generally larger and more slender, and have no flattening (except *Trichostrongylus orientalis* Jimbo from man in Japan) and are not known to have globules. This is not the egg of *Trichostrongylus orientalis* in either dimensions or proportions, and that species has no globules (in photomicrographs and descriptions).

No ova of like structure have been found by us on examination of feces of horses, mules, cattle, hogs, goats, or culture rats and mice from Texas.

The infected soldiers were examined for the most part within two or three weeks after admission from civil life; hence the infection may be attributed to the region of their previous residence. The distribution has been determined on the basis of the place of enlistment of the infected soldiers. In 30,348 examinations made between July 28 and Aug. 21, 1918, there were 361 cases of infection among troops in Camp Travis. These came from forty-eight states of the Union with infections in twenty-two states. The number of men examined, the number of infections, and the percentage of infection in each state from which infected men came are given in the accompanying table.

---

[1] Cobb: Proc. Linn. Soc., N. S. Wales, 5, 1890.

The regions from which no infections were detected are the New England states, the Southeastern states, and a group in the Central Northwest.

In Texas the sandy prairies, the eastern timber belt, and especially the eastern and western cross timber countries, narrow belts of sandy soil running south from the Red River through the most densely populated region of the state, are the most heavily infected regions. The percentage of infection in men from counties in these belts ranges from 1 to 11. These are also regions of heavy hookworm infection. This suggests entrance by skin penetration.

Negroes, as in the case with hookworm infections, have a lighter infection (0.9 per cent) than white men (1.5 per cent). Men of foreign birth show infections, but there is no suggestion of importation. No occupational relationship to infection is evident. Men from country and city are both infected, though the greater part of the cases come from the country and smaller towns.

There is a very marked seasonal occurrence in the appearance of the ova. Examinations have been in progress from March to November inclusive, but 409 of the 429 infections were detected between July 28 and September 8, 301 of them in sixty-one of the ninety-two companies of the 165th Depot Brigade, and the remaining 108 in other organizations of Camp Travis. This period of maximum oviposition follows about two months after the maximum use of fresh salads, such as lettuce and radishes, in the usual course of country and town life. The interval is approximately that required for other nematodes, such as hookworm, for reaching sexual maturiy after entering the host. Oviposition is exceedingly irregular. Stools of infected men contain ova rarely. The possibilities of a much larger percentage of infection is suggested by this fact. No cause for cessation of detections of infections is apparent. It is possible that the parasites die or are cast off after maturity, but evidence is lacking. A few cases of infection have been detected throughout the remainder of the year except from December to February, which period has not as yet been covered.

ORIGIN OF INFECTION

State	No. of Men Examined	Infections Number	Infections Per Cent.
Arkansas	156	4	2.6
California	85	2	2.3
Colorado	937	36	4.0
Illinois	654	7	1.1
Iowa	218	5	2.3

Texas	21,623	213	1.0
Utah	13	1	7.7
Virginia	22	1	4.5
Washington	24	1	4.2
Wisconsin	84	1	1.2
Totals	29,053	361	1.2

The possibility of chance infections of food and water by ova have been carefully considered. Camp Travis is supplied with nonstored artesian water. Camp sanitation tends to preclude food infection from manure or from rodents. Ova of plant nematodes presumably have no antidigestive ferments. Similar ova to this have not been reported from food plants. The ova change appearance on cooking.

In the premises it seems probable, but not proved till the adult is found, that these ova come from an *Oxyuris* parasitic in but perhaps ill adapted to man, with marked seasonal limitation in oviposition. The variations in proportions and size of ova, and the irregularities of deposition suggest a small adult worm, and possibly a location in the appendix or ducts of the liver. *Oxyuris* is usually a parasite of the cecum in rodents. Appendixes should be examined for this hypothetic parasite. Immunity from vermifuges and enemas tends to confirm this supposition. There is a possibility that the worm is a small one, easily killed by treatment, and perhaps digested before its discharge.

CLINICAL OBSERVATIONS AT CAMP TRAVIS BASE HOSPITAL

Observations were made in forty-seven cases in which unidentified nematode eggs had been found.

In Cases 1 to 6 there were positive findings of eggs in the stools after the patients came to the hospital and before treatment, the eggs disappearing entirely from the stools after one administration of 30 c.c. of a saturated solution of magnesium sulphate.

In Cases 7, 10 and 11, enemas of benzin were given in the strength of 15 minims to the liter. No eggs were found in the stools after the first enema. All were positive before that administration.

In Cases 8 and 9, the benzin enemas were given on three successive days, after which ova were still present in the stools. The patients were then given castor oil, followed by 30 grains of thymol, which in turn was followed by benzin enemas. Ova were still present in the stools after these treatments. The patients were then given 30 c.c. of a saturated solution of Epsom salt, after which the ova were not found.

In Cases 12 to 18, oil of chenopodium was given by the method in use in the government hospitals, that is, magnesium sulphate, 30 c.c., at 4 p. m., followed by a cereal supper, a glass of milk at 6 a. m. the following day, and 0.4 c.c. of oil of chenopodium at 7, 8 and 9 a. m., with magnesium sulphate at 11 a. m. No ova were found in the stools after the treatment.

In Cases 27 to 32, ova were present in the stools on admission to the hospital, but these patients were not treated for four days. They were given a full tray diet, and daily examinations made of the stools. The eggs disappeared in from one to three days. They were then given a vermifuge: three of them thymol, 1 dram in broken doses (three) in emulsion and three oil of chenopodium, 40 minims, in broken doses (three) in emulsion.

In Cases 33 to 38, the patients were put on a vegetable diet, with the prompt disappearance of the ova, and then given a cathartic.

In Cases 39 to 43, the patients were placed on a meat diet with the same result.

In Cases 44, 45 and 46, the patients were given 5 minims of turpentine after a cathartic, although no ova were found in the stool after admission to the hospital.

In Case 47 numerous eggs in the stools were reported before coming to the hospital, but none were found in the stool since. This patient was given first a plain enema, and on the following day a soapy water enema, and on the next day magnesium sulphate, 30 c.c. of a saturatel solution, after which for two days he was given naphthalene in 7 grain doses, four times daily for two days.

In none of the foregoing cases were any parasites recovered, although repeated examinations of the stools were made in every case both during and after treatment, by washing through a 50 or 80 mesh sieve in many instances.

The blood counts in every case were all well within normal limits except that in Case 9 there was evidence of a secondary anemia; this patient, however, had been in indoor work and gave evidence of a former tuberculous process. In Case 47 the eosinophil count was 5, a little above normal. However, in thirty-two of the forty-seven cases the larger mononuclears showed a slight increase above normal.

Stomach washings in four cases showed no evidence of either ova or parasites.

In none of the cases was there any evidence in the history, symptoms or physical examination pointing to an infection by intestinal parasites.

BERIBERI AT U. S. ARMY BASE HOSPITAL, SAN JUAN, PORTO RICO

LABORATORY INVESTIGATIONS AND CLINICAL MANIFESTATIONS OF SIXTY CASES

JOHN D. RIDDELL, M.D. (SALINA, KAN.)
Major, M. C., U. S. Army; Commanding Officer

CHARLES H. SMITH, M.D. (UNIONTOWN, PA.)
Major, M. C., U. S. Army, Chief of Medical Service

AND

PEDRO GUTIERREZ IGARAVIDEZ, M.D.
Captain, M. C., U. S. Army; Chief of Laboratory Service

SAN JUAN, PORTO RICO

When cases of polyneuritis began to come into the base hospital at San Juan, from Camp Las Casas, Porto Rico, it was a serious question to decide whether they were those due to dietary deficiency or the result of specific infections, as we had just passed through a serious epidemic of influenza; but after a careful study of the clinical manifestations and complete laboratory reports, it was quite evident to all those who followed the investigations that we were dealing with beriberi, as seen in the Orient. This is the first time, as far as we have been able to determine, that beriberi has been diagnosed as such, in the island of Porto Rico.

The sanitary inspector of the camp was asked to secure and furnish us with a complete detailed report of the diet of the 373d Regiment, from which regiment we were getting the majority of our cases.

The investigation and report of the food used by Company A, Company B, Company C and Headquarters Company of the 373d Regiment, revealed that:

A. Polished rice was a staple article of food for the foregoing companies during the months of September, October and November, 1918.

B. It was served on an average of two meals a day during that period.

C. While the ration was well balanced, there was a deficiency in fresh vegetables due to local conditions.

D. The only vegetables served in large quantities were potatoes and the different varieties of beans.

E. A large amount of canned meats and canned vegetables were used, especially by Company B of the 373d Regiment, which company furnished a majority of the beriberi cases.

On questioning the patients suffering from beriberi, it was learned that those affected were rice eaters and consumed their full rice component of the daily ration, 3.3 pounds a week. Most of them did not eat their meat ration, and those who did eat meat ate sparingly of it.

The following extract from the Section of Tropical Medicine and Hygiene on the Seventeenth International Medical Congress is quoted:

> The section is of the opinion that beriberi among natives who live principally on rice is brought about by the continued and too exclusive use of rice, submitted to a too complete milling, which removes the cortical and subcortical layers of the grain.

LABORATORY INVESTIGATIONS

1. *Blood.*—The average percentage of hemoglobin in forty-seven patients suffering from beriberi or polyneuritis was 72.64.

The differential count in twelve cases showed an average in polymorphonuclears of 45.83 per cent. and in small mononuclears of 38.75 per cent.

2. *Urine.*—The examination of urine in thirty-nine patients disclosed no albumin. Of this examination 38.46 per cent. disclosed hyaline casts and 15.38 per cent. hyaline and granular casts.

3. *Feces.*—Of these examinations, 90.47 per cent. revealed uncinaria ova, in a few instances associated with other parasites.

4. *Swabs.*—In swabs from the throats and noses of thirteen patients inoculated in proper mediums, nothing important was detected.

5. *Spinal fluid.*—In Case 12 (Reg. No. 5861) the spinal fluid was clear and showed 3 white cells, 14 red cells and 3 cells undetermined to the cubic centimeter.

6. *Necropsy.*—The examination of L. M. (Reg. No. 5937) resulted in these findings:

> The body was well developed. Rigor mortis was fairly well marked. There was edema of the lower extremities, especially of the ankles. The face was cyanotic, with a large amount of foamy secretion coming from the mouth and nose. Hypostatic congestion was well defined. When the thorax was opened, fluid blood of dark color escaped through the injured vessels with ease. Considerable edema was noticed on both lungs. On section the lungs showed signs of edema. The pleural cavities of both sides contained a moderate amount of fluid. The pericardium contained about 2 ounces of fluid. The heart was large, especially the right heart, where there was considerable thinning of the walls, with very marked dilatation. The thoracic vessels were normal. The diaphragm was well developed. The liver was somewhat enlarged but of normal appearance and consistency. Section did not show any internal macroscopic change. The pancreas was normal. The stomach and intestines were normal. No parasites were found in the ileum. The spleen was somewhat diminished in size, but did not show any macroscopic change. The omentum was rather reduced in size. The kidneys showed some degree of congestion. No macroscopic change could be found in the brain, meninges and upper portion of cord. The cerebrospinal fluid was clear. The penis had a long prepuce. The scrotum was edematous.

7. *Cultures.*—Cultures made from the heart and lungs at postmortem were negative.

8. *Microscopic examination.*—Preliminary microscopic examination of the spleen, heart, kidneys and liver sustained the macroscopic appearance.

CLINICAL MANIFESTATIONS AS FOUND ON EXAMINATION OF SIXTY CASES OF POLYNEURITIS

Symptoms began in almost every case with a numbness over the legs, usually over the shins first and gradually spreading over the calves and upward to the knees, over the thighs and then to the abdomen between the umbilicus and symphysis pubis. In some cases it also affected the upper extremities, usually the finger tips, and extended upward, to the hands, forearms and in a few cases, to the arms.

TABLE 1.—FINDINGS IN POLYNEURITIS CASES.

1. Legs, only	22
2. Legs and thighs	6
3. Legs, thighs and abdominal wall	6
4. Legs, thighs, abdominal wall and hands	3
5. Legs, thighs, abdominal wall, hands and forearms	9
6. Legs and abdomen	3
7. Legs, hand and forearms	6
8. Legs, thighs, hands and forearms	3
9. Legs, *abdominal wall, hands* and forearms	1

Hyperesthesia:	
Legs	5
Thighs	2
Arms	2
Had influenza:	
Last two months	17
Last six months (previous to the last two months)	5
Doubtful	4
Not influenza	36

Pain was noticed in every case in the calf muscles, and in nearly every case was first noticed in this area. The peroneal group was next in order of frequency and time to be affected. Of the thigh muscles, the quadriceps were first and also more severely affected, with the hamstring group next and adductor group last. Intense pain was caused by pressure on these affected muscle groups. There did not seem to be any greater degree of tenderness over the course of the large nerve trunks.

Only about one third of the patients had any pain in the hands, and the tenderness on pressure was not marked, the thenar eminences being most tender. The flexor muscles in the forearms were the most tender in that area.

Edema was noticed to a small degree in thirty-four cases. This was localized in the ankles and over the tibias, but disappeared after a few days in bed. Two patients had general edema, though not very marked, on admission, but this also disappeared after a few days in bed. The urine in these cases was negative to albumin.

Areas of partial anesthesia, in some cases being only a blunted sensibility, were found in over half of the cases. The part most affected was the shins, other parts of the leg together being but slightly more affected than the shins alone. The feet, abdomen and thighs were affected in the order named, with a few areas in hands and forearms. Hyperesthesia was found in nine cases.

Absence of fever was very noticeable; only eleven patients had some slight fever at the onset, which lasted but a few days. Gastric disturbance was still less frequent, only seven cases of nausea, or nausea and vomiting, being recorded, and this at the onset for but a few days. Complete anorexia was reported as beginning symptoms in four cases, and this was improved either when the patient had been admitted or after a few days in the hospital.

Some form of cardiac affection was found in only twelve cases, consisting in tachycardia, enlarged heart, or a murmur. Whether these were complications of the disease or existed previous to the disease cannot now be told.

The patellar reflex was absent in twenty-six cases, diminished in twenty-six and the Romberg phenomenon was present in forty-six cases. Incoordination could be determined in these cases by other means.

Korsakoff's syndrome was absent in every case.

Thirty-three of the patients reported that they had not had influenza in the present epidemic. Seventeen did have, and six had that disease in the epidemic four months before.

Two patients were admitted with attacks of acute dyspnea. Both had general edema, with rapidly progressing edema of the lungs. The heart action was rapid and very feeble; and heart was enlarged downward and to the right and left. Their feet and hands were cold, and gradual increasing cyanosis was present from the time they entered the hospital. Acute distress was most marked, and nothing could give relief. The patients gasped for breath, were intensely restless, and at times were wild with agony. Death occurred in both cases before twenty-four hours in the hospital had elapsed.

All patients began to improve when placed on a high protein diet, and practically no medication was given. The surgical management of the cases consisted in relieving all tension on muscles showing even a slight trace of paralysis. Six patients when received showed a marked degree of equinovalgus. The affected muscles in these cases were put at rest by the application of a light plaster cast extending well on to the toes, holding the foot at right angles to the leg; the cast was removed as soon as the foot drop symptoms disappeared. All but one patient on a highly nitrogenous diet promptly regained normal function of muscles involved. Thirty-two patients still remain in the hospital under treatment.

TABLE 2.—PERIOD OF SYMPTOMS PREVIOUS TO ADMISSION TO HOSPITAL.

One, unknown, came to the hospital with influenza and developed pneumonia.

Well Born.—Children will never be well born until they are desired by the men and women who are potential parents.—Dawson.

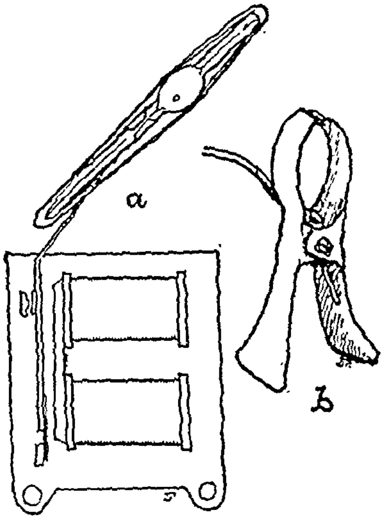
Clinical Notes, Suggestions, and New Instruments

A SIMPLE SHAKER FOR HEMOCYTOMETER PIPETS

Tracy Jackson Putnam, A.B., Boston

Having had occasion recently to make a large number of blood counts, I became impressed not only with the necessity of shaking the pipet thoroughly in order to obtain accurate results, but also with the time and exertion required to shake by hand. I accordingly devised an electric shaker.

The gong and ball of the hammer were removed from an ordinary electric bell, and a small spring clip, such as is used for hanging up negatives, was soldered to the end of the striker arm. The jaws of the clip were bent so as to hold a pipet securely, and it was placed in line with the long axis of the bell, but at an angle of 45 degrees with it, by bending the striker. Such an apparatus may be screwed to the laboratory table and operated by two dry cells with a switch in circuit; or it may be fastened to the cover of a box measuring approximately 5 by 3 by 2 inches, containing two double-cell flashlight batteries, connected in series-multiple by a spring plate at each end. The bell frame should be firmly fastened, as any lost motion ruins the efficiency of the machine.



Simple shaker for hemocytometer pipets: *a*, pipet, enclosed in rubber band, in shaker; *b*, detail of clip.

The filled pipet is kept from leaking by a rubber band, cut from a 3½ inch automobile inner tube, around the ends, which also serves to hold a bit of paper indicating the source of the specimen. It may be kept thus for hours or even days. The contact points and the length of arm of the shaker should be so regulated that the glass bead can be seen to spin in the ampulla. The pipet should be shaken for from three to five minutes, which can meanwhile be profitably spent in putting an extra polish on the counting cell and cover glass.

A trace of grease from a grease pencil, in the gutter of the slide, tends to keep the drop from overflowing.

108 Marlboro Street.

Child Labor Bill and the States.—The National Child Labor Committee calls attention to the fact that the war has left us a legacy of greatly increased employment of children in industry, in the state of Pennsylvania this amounting to 60 per cent. increase among children between 14 and 15 years of age. This probably represents the condition throughout the country. The Pomerene child labor measure which has passed the United States Senate would apply only to children in the manufacturing and mining industries, in which are found but 15 per cent. of working children from 10 to 15 years of age. This leaves much for the states to do to protect the remaining children, none of whom, according to the committee, should be allowed to engage in gainful occupations under the age of 16. To help out, children's scholarships and mothers' pensions to enable boys and girls of needy families to go to school are advocated. Mothers' pensions or compensation laws are in force in thirty-three states, Illinois being the first to enact such a law. These laws help to avoid the hardship resulting from child labor laws on families in which the wages of the children are needed for the family support on account of the death or desertion of the man wage earner, and they protect the children.

Therapeutics

MALARIA

There have always been malarial fevers, under the scourge of which even nations have deteriorated. In more recent times, industrial, engineering, financial and military failures have occurred on account of malarial fever. Especially in evidence was the failure of the French to dig the Panama Canal as the result of this infection. On the other hand, the power of prevention has never been shown so completely as it was on the isthmus under the sanitary administration of General Gorgas.

As general measures of prevention are matters of state and sanitary legislation, they need not be described here.

The most important single measure is the prevention of mosquito bites, even if the majority of such bites are not due to the anopheles mosquito. This means not only the eradication of local mosquito-breeding spots, but also the proper screening of houses, sleeping porches and tents.

It has long been considered that prophylactic doses of quinin would prevent the growth of the germ, if the patient received such an infection; therefore enormous quantities of quinin have been administered, in different parts of the world, especially to soldiers or others visiting malarial districts.

We should recognize that the constant ingestion of such a protoplasmic poison as quinin may not be to the advantage of the individual. It is an appetizer and a stimulant, but at the same time it may inhibit many cellular and glandular activities. No one can doubt that if a person has quinin circulating in his blood, and at that time receives a bite from an infected mosquito, the germs will not grow; but at present the evidence seems to be accumulating that it is better to prevent the bites of the mosquitoes than persistently to take prophylactic doses of quinin.

While the clinical diagnosis of typical malarial fever (chill, fever, headache, often vomiting, sweating and remission) is readily made, without the characteristic symptoms it may be difficult, and many times can be made only by finding the plasmodium in the blood. The peripheral blood may not show the plasmodia in latent malaria. It should also be remembered that malarial organisms may remain harbored in the blood or in some other part of the body for an indefinite period, and perhaps later reinfect the carrier or an anopheles mosquito, and thus pass the infection on to some one else.

In most parts of this country, so-called pernicious malarial fever is rare. Consequently, most infections of malaria are cured by the administration of quinin by the mouth. The adult germs are readily killed by this drug; but it is more difficult to kill the germs in spore. In serious or old infections, the administration of quinin does not seem to prevent the malarial germs from lying dormant in some part of the body, probably in the spleen. Such dormant germs cause recurrent infections.

There are two methods of administering quinin in acute infection. One method is to give the largest dose five or six hours before the expected chill, at which time the germs are mature and therefore most readily killed by the drug. The other method is to give the quinin in smaller doses every two or three hours, night and day, for three days. Whichever method is used, there should be an intermission for the patient to eliminate the quinin and free himself of this poison—and quinin should be considered a poison of the milder type. When quinin is given continuously for three days, as just suggested, it should be stopped for about a week and then repeated. If the quinin is given in larger doses six hours before the expected chill, the amount should be 5, 10 or 15 grains. It is best administered in soluble capsule, and should never be given on an empty stomach, but with milk, malted milk, bouillon and crackers, or tea or coffee and toast, as some simple food should be in the stomach to prevent irritation from the quinin. No more quinin should then be given for twenty-four hours, and then about half the first dose is given on the intermediate day (the amount entirely depending on the severity of the infection and the age of the patient). Then again the larger dose should be given six hours before the time of the next expected chill, whether or not the previous chill occurred. The dose of quinin may then be gradually decreased daily until at the end of a week of freedom from chills a tonic dose of the drug, as 2 grains, combined with 1 grain of iron and $\frac{1}{30}$ grain (0.002 gm.) of arsenic may be given, in capsule, three times a day. This may be given for one or two weeks and then gradually reduced.

If the more intensive treatment is given—administration every two hours—it would be better to use a more soluble form than the sulphate, such as the bisulphate or the hydrochlorid, and the dose should be 2 grains every two hours, or 3 grains if given every three hours. This may be given in solution or in a soluble capsule. It should always be taken with plenty of water. At the end of the three-day period when the quinin is stopped, it is well to give arsenic and iron in some form.

It seems to be always advisable to give a cathartic, if possible, before beginning intensive quinin treatment. The one most frequently given is calomel.

As malarial infection in temperate climates is not a dangerous infection, it is well to consider somewhat the comfort of the patient during treatment. In other words, administration of quinin during the fever period, with a throbbing head and nausea, is unnecessary. When the patient is first seen during the chill, the indication is to get him warm as quickly as possible. Hot drinks, such as hot lemonade or hot tea, should be given, and he should be surrounded with hot water bags. As soon as the fever starts, a more desirable antipyretic than quinin should be given; 0.2 gm. of acetanilid, or 0.75 gm. of acetphenetidin may be given to hasten the stage of perspiration and lower the temperature. As soon as the patient is freely perspiring and the headache has disappeared, the quinin treatment by small doses frequently given may be begun. Or, if the method of larger doses with a longer time between the doses is preferred, some drug that will prevent the unpleasant cinchonism should be coincidently administered. A drug well suited for this purpose is sodium bromid, and 3 grains of it for every grain of quinin sulphate will generally prevent cinchonism.

The value of arsenic in driving plasmodia from hiding, eliminating infection and preventing recurrences seems to be proved; hence its suggested addition to the quinin treatment.

IDIOSYNCRASY TO QUININ

When there is known to be marked idiosyncrasy against quinin, as shown by serious cerebral excitement, serious ear and eye symptoms, and even swelling of the tongue, puffing of the face, and eruption on the skin, some substitute must be used in the treatment of malaria. One of the best substitutes is arsenic in the form of liquor potasii arsenitis (Fowler's solution). Another successful substitute is methylene blue. The dose of arsenic must be large, to the point of causing stomach irritation and some diarrhea. Arsenic would not be advisable if there was nephritis, or even albuminuria. The dose of methylene blue is from 0.1 to 0.2 gm. every four hours, or 0.3 gm. three times a day, after meals. It should be given in capsule and taken with plenty of water.

Fortunately, few persons show such serious idiosyncrasy against quinin as to need these substitutes. A few patients who are especially susceptible to the first dose of quinin tolerate it well after the first twenty-four hours.

PERNICIOUS MALARIAL FEVER

This type of fever, often called congestive chill, means a serious infection, dangerous to life. Very large doses of quinin are necessary, and generally the quinin is best administered intramuscularly, or perhaps intravenously. The clinical course of the disease must be immediately stopped; a second, and certainly a third chill must be prevented.

HEMOGLOBINURIC FEVER

The germ of infection of this blackwater fever has not been found, but is generally more or less closely associated with ordinary malarial plasmodia. It has been thought that the parasite of this disease destroys the parasites of ordinary malaria.

The advisability of giving quinin during this disease is still somewhat in doubt, although some physicians practicing on the isthmus believe that large doses of quinin should not be given during this fever. Quinin may perhaps never be the cause of hemoglobinuria; on the other hand, it has been reported to increase the destruction of blood corpuscles and the loss of blood during hemoglobinuric fever.[1]

---

[1] A discussion of this subject, with many references, has been presented by W. O. Ott (J. A. M. A. **67**: 872 [Sept. 16] 1916).

Industrial Morbidity Statistics.—*Public Health Reports*, Aug. 30, 1918, contains a synopsis of a report of a Committee on Industrial Morbidity Statistics of the American Public Health Association, which is to be presented before that body at its meeting in Chicago, Oct. 14-17, 1918. A complete plan for collecting, tabulating and employing these statistics, together with outlines of proposed analytic tables, is presented. It is recommended that the United States Public Health Service be made the clearing house for the collection, analysis and publication of the statistics. The committee consists of Louis I. Dublin, chairman; Carl B. Auel, William A. Hathaway, Dr. George E. Tucker, and Dr. B. S. Warren, secretary.

New and Nonofficial Remedies

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION. W. A. PUCKNER, SECRETARY.

BIOLOGICALLY REACTIVE FOOD PROTEINS

These products represent the purified and concentrated proteins of the particular food from which they are obtained.

Preparation.—They are prepared from the protein bearing portions of the particular food by extracting fats and lipoids with suitable solvents. The dry residues are then extracted with such solvents as water, dilute alkaline or acid solvents, as may be indicated. The protein is obtained from this solution after neutralization if necessary, either by rapid evaporation of the solvent at low temperature or by concentrating the solution and precipitating the protein by a suitable agent such as alcohol, acetone, etc.

Properties.—In any case the protein is obtained in the form of a dry, finely divided powder which is white or nearly so and wholly or partly soluble in water.

Actions and Uses.—These protein products are used in cases where persons show a peculiar hypersensitiveness or idiosyncrasy toward certain articles of the dietary. Their use is twofold, namely, to establish just what particular food produces the untoward symptoms, and also by their proper application to immunize the patient against the ill effect of this food.

The test for sensitiveness is made by scarifying the skin in such a manner as just to penetrate the outer layer, taking care not to draw blood. The protein is then rubbed into the tissue at this spot either in the form of dry powder or as a solution in sterile water or physiological sodium chloride solution. If desired, a much more dilute solution (1 to 100 or less) of the protein may be injected *intradermally* in doses of one hundredth to two hundredths of a cubic centimeter. Controls with sterile sodium chloride solution should always be made regardless of the method of application employed.

The reaction will appear about the site of inoculation in the form of a distinct urticarial wheal within five minutes to half an hour, and may persist for several hours. The intensity of the reaction will depend somewhat upon the concentration of the protein solution. No systemic effect should be produced.

When the identity of the particular food protein causing the symptoms is thus established, it has been found that the patient may be desensitized by the administration of gradually increased amounts of food containing the offending protein or of the isolated food protein itself. If the isolated food proteins are used, they are best administered mixed with the ordinary foods. The dose at first should not exceed five to ten milligrams given several times a day whenever food is taken. The dose may be increased but should be governed by the appearance of systemic disturbances. The skin reaction is the best indication as to the effect being produced by the dosage given. The administration should be continued until no positive skin reaction is obtained by the same protein which is being administered.

The efficiency of the treatment can be judged by the patient's ability to ingest without ill effect large quantities of the food protein which previously had produced the untoward symptoms.

COW'S MILK ALLERGENS-SQUIBB.—A powder representing all the soluble proteins contained in cow's milk.

Actions and Uses.—See preceding general article on Biologically Reactive Food Proteins.

Dosage.—See preceding general article on Biologically Reactive Food Proteins.

Manufactured by E. R. Squibb & Sons, New York. No U. S. patent or trademark.

Cow's Milk Allergens-Squibb is prepared: Fresh cow's milk is centrifuged to remove fat and dialyzed to remove lactose and salts. From this solution, the milk proteins are precipitated by saturation of the solution with ammonium sulphate and the salts then removed by filtration and dialysis. The remaining protein solution may now be reduced to dryness by rapid desiccation at a low temperature in vacuo or the proteins may be precipitated by addition of alcohol or acetone and the precipitate washed and air dried. Alternate method: The milk protein solution obtained by removal of fat, lactose and salts as in the first method, is mixed with alcohol or acetone. The precipitate produced is extracted with anhydrous alcohol or acetone and ether.

It is a fine, white, odorless powder, somewhat soluble in water and physiological sodium chloride solution. It is more freely soluble in dilute sodium carbonate or sodium bicarbonate solution.

If 3 Cc. of a solution of cow's milk Allegerns-Squibb in water (1-100) be made alkaline by sodium hydroxide, and a drop or two very dilute cupric sulphate solution added, the whole well mixed and allowed to stand at room temperature for ten minutes the clear fluid above any precipitate which may have formed assumes a violet tinge (biuret reaction).

If to 3 Cc. of a solution of cow's milk Allergens-Squibb in water (1-100) 3 Cc. of glyoxylic acid be added and then 4 to 5 Cc. concentrated sulphuric acid added in such a manner as to make a separate and distinct layer, a violet color develops at the zone of contact (Hopkins-Cole reaction).

Cow's Milk Allergens-Squibb.—Produces specific precipitins in animals.

Cow's Milk Allerpens-Squibb.—Produces specific immunity or anaphylactic reactions in animals.

EGG ALLERGENS-SQUIBB.—A powder representing all the soluble proteins contained in hens' eggs.

Actions and Uses.—See preceding general article on Biologically Reactive Food Proteins.

Dosage.—See preceding general article on Biologically Reactive Food Proteins.

Manufactured by E. R. Squibb & Sons, New York. No U. S. patent or trademark.

Egg Allergens-Squibb is prepared: The shells are discarded and the whites and yolks collected separately. The proteins of the egg white are extracted by dilute sodium chloride solution. From this solution the proteins are obtained after removal of sodium chloride partly by dialysis, by rapid evaporation in vacuo at low temperature or by pouring the protein solution freed from sodium chloride into ten times its volume of acetone or strong alcohol and dehydrating by washing with absolute alcohol or absolute acetone and absolute ether. The other soluble material of the yolks is removed and from the residue the proteins are extracted with sodium chloride, dilute sodium carbonate, or sodium bicarbonate solution. This protein solution is reduced to dryness by rapid evaporation in vacuo at low temperature or it may be precipitated by pouring the solution into ten times its volume of strong acetone or alcohol. In the latter case, it is further dehydrated by extraction with absolute alcohol, absolute acetone and absolute ether. The dehydrated egg white protein and the protein of egg yolk are mixed in equal proportions.

It is a fine white powder, odorless, somewhat soluble in water, and physiological sodium chloride solution. More freely soluble in dilute sodium carbonate or sodium bicarbonate solution.

If 3 Cc. of a solution of egg allergens-Squibb in water (1-100) be made alkaline by sodium hydroxide, and a drop or two of very dilute cupric sulphate solution added, the whole well mixed and allowed to stand at room temperature for ten minutes, the clear fluid above any precipitate which may have formed assumes a violet tinge (biuret reaction).

If to 3 Cc. of a solution of egg allergens-Squibb in water (1-100) 3 Cc. of glyoxylic acid be added and then 4 to 5 Cc. concentrated sulphuric acid added in such a manner as to make a separate and distinct layer, a violet color develops at the zone of contact (Hopkins-Cole reaction).

Egg Allergens-Squibb.—Produces specific precipitins in animals.

Egg Allergens-Squibb.—Produces specific immunity or anaphylactic reactions in animals.

WHEAT ALLERGENS-SQUIBB.—A powder representing all the soluble proteins contained in wheat.

Actions and Uses.—See preceding general article on Biologically Reactive Food Proteins.

Dosage.—See preceding general article on Biologically Reactive Food Proteins.

Manufactured by E. R. Squibb & Sons, New York. No U. S. patent or trademark.

Wheat Allergens-Squibb is prepared: Wheat flour is extracted with sodium chloride solution. The clear solution so obtained is saturated with ammonium sulphate. The precipitated proteins are collected and dialyzed to remove inorganic [illegible] tein solution is brought to dryness by any [illegible] or cow's milk allergens-Squibb and egg [illegible] gluten, freed from starch, is extracted with 90 per cent. alcohol to remove gliadin. The gliadin is obtained by pouring a strong alcohol solution of it into absolute alcohol. The precipitate is dehydrated by washing with absolute alcohol and ether. This gliadin is rendered soluble by treatment with dilute sodium carbonate solution. From this solution the soluble gliadin is precipitated by any of the methods described under cow's milk allergens-Squibb and egg allergens-Squibb. The two protein preparations thus obtained are mixed to produce wheat allergens-Squibb.

It is a granular powder, nearly white, odorless, somewhat soluble in water, and physiological sodium chloride solution. More freely soluble in dilute sodium carbonate or sodium bicarbonate solution.

If 3 Cc. of a solution of wheat allergens-Squibb in water (1-100) be made alkaline by sodium hydroxide, and a drop or two of very dilute cupric sulphate solution added, the whole well mixed and allowed to stand at room temperature for ten minutes, the clear fluid above any precipitate which may have formed assumes a violet tinge (biuret reaction).

If to 3 Cc. of a solution of wheat allergens-Squibb in water (1-100) 3 Cc. of glyoxylic acid be added and then 4 to 5 Cc. concentrated sulphuric acid added in such a manner as to make a separate and distinct layer, a violet color develops at the zone of contact (Hopkins-Cole [illegible]

Wheat [illegible]

Wheat [illegible] specific precipitins in animals.
[illegible] specific immunity or anaphylactic reactions in animals.

THE LIMITATIONS OF WAR-TIME DIETS

Among large groups of persons, comprising literally millions, the exigencies of war represented by voluntary or compulsory rationing have enforced profound dietary changes. The numerous records of a decrease in body weight among civilian populations of affected districts bear witness to the fact that food restrictions of an unusual sort have undoubtedly been experienced by great numbers. In some cases the enforced situation has doubtless been one merely of marked economy in nutrition; but there is every reason to believe that actual undernutrition has occurred in many localities. Thus the war has given a new significance to the question as to the effect of such dietary conditions on the human organism.

Recently we referred to researches conducted both in Europe and in America with reference to the metabolism attending long restricted diet.[1] The decrease in body weight is accompanied by a lowered basal metabolism clearly indicated by the smaller respiratory exchange. Among the attendant phenomena very carefully studied by Benedict and his collaborators in their Springfield "war-starvation" experiments was the characteristic showing of the heart rate. Despite such pronounced changes induced by intentional undernutrition—or perhaps it should be designated purposeful loss of weight—the general health of the subjects appears to have remained surprisingly good. The losses of protein from the body had been very considerable.

These American observations covered a period of a few weeks. There is now available a report by the German physiologists Zuntz and Loewy[2] of Berlin, who have made observations on the effect of war rations on their own metabolism since the beginning of the war. In accordance with statements from von Müller's clinic in Munich they, too, report early losses of weight amounting to more than 10 per cent. The individual of smaller size evolved in this way by dietary restrictions undoubtedly is able to maintain himself on a lower level of nutrition than that represented for his size in prewar days of abundance. Like Jansen in Munich,[3] the Berlin investigators found that a stationary weight was reached after a time and nitrogen equilibrium became possible with an output of less than 10 gm. of nitrogen a day on the allotted war-time ration. In Jansen's subjects this was encountered with a daily intake of 2,100 calories in persons not exceeding 60 kg. (132 pounds) of body weight. The important rôle of a sufficient intake of calories is well illustrated in the case of Loewy. When his diet was reduced to between 1,500 and 1,800 calories, including from 50 to 60 gm. of protein (equivalent to 7 or 8 gm. of nitrogen) a day, his losses of nitrogen from tissue proteins were considerable, and continued unchecked until an addendum of 200 gm. of butter a day was instituted. Thus the laws of the conservation of energy are immutable—even during the patriotic observance of war-time restrictions.

Although it is evidently possible to keep alive through reduction of weight to a figure at which smaller maintenance rations suffice, the experience of Zuntz and Loewy during periods of work carries a sinister warning. They found that the expenditure of energy in an active effort at marching was decidedly larger than had been observed in earlier days when they were more adequately nourished. The increased consumption of oxygen both during the period of exercise and in the stage of recuperation immediately following was sufficiently striking to indicate the unfavorable effect of the undernutrition on muscular performance. This consequence deserves to be prominently noted, because many of the studies on restricted feeding have been concerned with the problem of maintenance alone without due regard to the economy and ease of work under the conditions investigated. The factor of safety may withstand the depreciating effect of a few days or even weeks; but months of enforced economy are likely to bring it nearer to the vanishing point where even moderate effort begins to involve a severe sacrifice.

THE DIAGNOSIS AND POSSIBLE NATURE OF HEMOSIDEROSIS

In this pathologic condition, to which von Recklinghausen gave the name of *hemochromatosis*, an iron-containing pigment, hemosiderin, is found deposited in various organs and tissues. The real significance of this substance, the chemical *nature* of which is not yet known, has never been discovered. In fact, the fate of *hemosiderin* seems still to be so uncertain that it is regarded most frequently merely as a waste disintegration product of the blood pigment, *hemoglobin*, though by some it has been assumed to play a part or be utilized in the manufacture of new red blood corpuscles.

Hemosiderosis does not manifest itself in any conspicuous way when such quantities of free hemoglobin as must arise in the usual wear and tear or physiologic hemolysis of blood cells find their way into the circulation. At any rate, hemosiderin is not discoverable in the organism by the usual modes of examination except after certain types of excessive hemolysis. Rous and Oliver[1] interpret the evidence hitherto available as indicating that under most circumstances of blood destruction the spleen and red marrow act as depots for hemosiderin and more than suffice for the purpose; but when the breaking down of red cells is fulminant, or large quantities of blood pigment are furnished the organism for a considerable period, the buffer activity of these organs is overcome, and some little hemosiderin is laid down elsewhere.

It is not easy to secure an "accumulation" of blood pigment in the organism experimentally under normal circumstances. If free hemoglobin is injected, it may be eliminated as such in considerable amounts through the kidneys. More striking results have been obtained by Rous and Oliver through the device of transfusing large quantities of blood at frequent intervals into animals. The foreign corpuscles are disintegrated; and in the midst of the plethora of fragments, considerable siderosis arises. According to researches at the Rockefeller Institute for Medical Research, the depositions are comparable to those of human hemochromatosis. In this disease, and likewise in pernicious anemia, the siderosis is found conspicuous in the liver, kidneys, pancreas and certain other organs; whereas in most cases of sudden hemolysis the pigment deposition occurs in the spleen, bone marrow, and sometimes in certain lymph nodes.

The explanation of the difference in the siderosis, that is, the unlike location of the pigment, in these different diseases has long been a mystery. It seems evident that when the deposition is highly specific, as in hemochromatosis, some tissue factor must be concerned in addition to the hemolytic reactions. Rous and Oliver venture this hypothesis: A liver cirrhosis of unknown origin leads to a failure of the organ to deal adequately with the iron-containing products of normal blood destruction, and the latter accumulate in the organism. Widespread pigmentation results automatically. It at length becomes so great as to cause the death of parenchymal cells, especially in the liver and pancreas, thus leading to secondary connective tissue overgrowth. This, in turn, through injury to the remaining parenchyma, hastens the accumulation of pigmentation. By a repetition of the vicious circle, what is essentially a chronic disease becomes at length a rapid progress down-hill. Diabetes appears in many cases as a result of the pancreatic injury, and soon death results.

The diagnosis of diseases like pernicious anemia and hemochromatosis involving a hemosiderosis has sometimes been extremely difficult, unless a conspicuous siderosis of the skin has developed. Necropsy usually reveals far more siderosis in the internal organs, but it cannot be detected during life. However, Rous[2] has ascertained that in disorders that bring about a siderosis of the kidney there are ordinarily present in the urinary sediment cells containing granules of hemosiderin, and often many free granules as well. The finding has proved useful in the diagnosis of hemochromatosis and will probably be of service in the recognition of pernicious anemia, and possibly some other diseases. Rous points out that urinary siderosis is an indication of a renal condition, not a disease. He suggests that the examination of urinary cells for iron pigment may prove to be a decisive method of determining the presence of hemochromatosis in doubtful clinical instances of cutaneous pigmentation.

SOME DESIRABLE NUTRITIVE QUALITIES OF FISH

The United States Food Administration is making earnest efforts to teach the American people to eat more of the many types of fish that are available, fresh, dried and canned. Although the possible supply of fish is practically unlimited, there are few species at most that have gained any considerable popularity as foods. The tilefish, grayfish, sable-fish, burbot and carp are some of the newer varieties now on the market. There are said to be available nearly seventy kinds of salt water fish and more than thirty fresh water varieties. Yet the average person knows not more than a dozen, and Langworthy[3] further avers that every year the fishermen of the Atlantic coast throw away 10,000,000 pounds of fish that have a higher nutritive value than New England's famous cod. Though our meat consumption is 170 pounds per person per year, we eat on the average only 18 pounds of fish apiece per year. Belgium and France are said to use even less, whereas in England the record mounts to 65 pounds per person.

There are various difficulties to be encountered in any attempted innovations of diet among large groups of people. One is the usual inertia or resistance to change that dietary customs or habits fix in persons. Another is the uncertainty regarding the real physiologic safety of the proposed change—the fear of an impaired nutritive value. Foods acquire deserved or undeserved reputations for wholesomeness or harmfulness in unexplained ways. The older plan of determining food values solely on the basis of chemical analysis in which proteins, fats, carbohydrates and calories per pound were ascertained has been supplanted to some extent by a physiologic mode of experimentation—by tests in which actual feeding experiments are made to give the clue to nutritive qualities. In this way the possession not only of the familiar proximate principles or nutrients but also of those less well defined properties that belong to the vitamins is demonstrable. The most reliable way now available of determining the value of a protein as a foodstuff is by studying the effect of administering it as a component of an otherwise adequate diet. This is the procedure employed so successfully by Osborne, Mendel, McCollum and their co-workers in ascertaining the comparative biologic value of many pure proteins for growth or maintenance. In this way Drummond[4] in England has investigated fish tissues and demonstrated that the coagulable proteins of the muscle tissue of cod, herring and canned salmon have a nutritive value as high as those derived from beef.

[3] Langworthy, C. F.: The Day's Food in War and in Peace, U. S. Food Administration, 1918, p. 58.

The discovery of Osborne and Mendel[5] that cod liver oil contains one of the vitamins—termed fat-soluble A by McCollum—which exerts a beneficial influence on the growth and health of the animal organism directs attention to the fishes from a different angle. The symptoms referable to the lack of this factor in the diet, among which the condition of xerophthalmia has been described, are said to be relatively scarce among fisher families.[6] Drummond has found, in possible explanation of this, that the so-called "fatty" fish, which contain considerable quantities of fat distributed throughout their muscle tissue, may serve as valuable sources of the important dietary essential, the fat-soluble vitamin. The herring is a particularly striking example.

No appreciable amounts of the water-soluble or antineuritic factor were detected in the muscle tissues of the fishes examined. Small amounts, however, were present in extracts prepared from the whole herring, having originated in all probability from the reproductive organs or other glandular organs. This is in accord with recent observations of Osborne and Mendel regarding the absence of any considerable content of the water-soluble vitamin from skeletal muscle, although glandular organs like liver and kidney possess it in abundance.[7] The newly acquired facts about the nutritive properties of fish thus serve to emphasize their food value at a time when beef—a prominent source of our protein supply—and butter or oleo fats—on which many depend for the fat-soluble vitamin—are not so abundant as in peace times.

PHYSICIANS' EXEMPTIONS FOR INCOME TAX

The blanks for the 1918 income tax returns are now being distributed. Each year since the income tax law was passed, the question has arisen: What constitutes the actual income of the doctor? Physicians, more than any other class of professional men, have heretofore confused gross and net income. Owing to professional habits, no dividing line has been drawn between personal and family expenses and expenses necessary for carrying on a practice. Few physicians have kept sufficiently accurate financial records to enable them to separate these two classes of expenditures. Under the income tax law, all actual expenses of carrying on a business may be deducted from the gross income. For the average business man, compilation of such expenditures is easy; for the physician, it is difficult; and in many cases, through ignorance or carelessness, the physician does not credit himself with all the exemptions to which he is entitled. The Internal Revenue Department has ruled that everything that constitutes an actual expense for the transaction of business can be deducted, but that those articles that are purchased as equipment constitute investment and not business expense. Under this ruling, which is eminently fair, the original cost of an automobile used for professional purposes is an investment and cannot be deducted; but the expenses of repairs, upkeep, garage, gasoline, oil, and chauffeur's salary are legitimate expenses that may be deducted. Under this ruling, the following items would be regarded as legitimate deductions: office rent, heating and lighting; office attendants, including office girl or boy, nurse or assistant; office telephone; drugs, dressings, bandages and all material that is to be consumed or expended in the treatment of patients, but not instruments, appliances, office furniture, etc., that are purchased for permanent equipment. Medical journals are a current expense and the subscription price may be deducted, but books are purchased as a permanent addition to one's library and are an investment, the price of which cannot be deducted. Dues in medical societies and organizations, and expenses in attending professional meetings, are legitimate deductions. This fact is understood by few physicians. All the expenses of keeping up and operating an automobile or of maintaining horses, carriages, sleighs, etc., that are used solely for professional purposes may be deducted, but not the original cost of these articles. If an automobile, a team of horses or a carriage is used partly for professional purposes and partly for personal and social use, then the expenses of upkeep should be prorated.

Regarding home expenses, if a physician's office is located in his house and if the house servant devotes any amount of time to assisting the doctor in his work, as office attendant, a proportionate amount of the servant's wages may be deducted. A proportionate amount of rent, heat and light may also be deducted. The cost of a house telephone may be prorated in proportion to the amount of professional and personal service. Depreciation on automobile, office furniture and equipment and other property necessary for carrying on professional work may also be deducted, provided the amount charged off for depreciation in any one year does not exceed the original cost of the article divided by the number of years in which it may be used. For instance, if an automobile cost $4,000 and is used eight years, *no more* than $500 a year depreciation can be charged off.

[7] Osborne, T. B., and Mendel, L. B.: Nutritive Factors in Animal Tissues, I, J. Biol. Chem. 32:309, 1917; II, ibid. 34:17, 1918.

The general principle underlying the income tax law is that each person should pay a tax on his actual personal income for the year, that is, what is left to him for the use of himself and family after deducting all the legitimate expenses of carrying on his business. Physicians heretofore have not availed themselves of exemptions to which they were entitled and have probably, in the majority of instances, paid taxes on a larger sum than their actual net income. Careful study of the instructions, accurate bookkeeping, and care in making up the returns will result in a considerable saving, which is perfectly legitimate and fair under the law.

THE OCCURRENCE OF PRECURSORS OF METHYL ALCOHOL IN NATURAL FOODS

It is not generally known that methyl alcohol, in what might be termed the potential form of methyl esters and methyl ether, is widely distributed in plant products that enter into the dietary of man. Thus the juices of many fruits contain such compounds; and when they are fermented, methyl alcohol may be liberated to the extent of 1 per cent. of the entire alcohol content formed. The reaction is not associated with the fermentation of the sugars present, but is connected with changes in the residual plant tissues from which the juices are obtained. The so-called pectin substances seem to be the mother substance. Therefore, when fermented fruits are distilled to produce such beverages as brandy, small, yet detectable quantities of methyl alcohol pass into the distillate along with the ethyl alcohol that forms the essential active ingredient of such distilled liquors.

Despite the fact that the pectinous parts of many edible plant forms—green vegetables, fruits and tubers—readily yield small quantities of methyl alcohol, everyday experience shows that these are no menace to the welfare of the body. Nevertheless the traces of alcohol thus ingested are not burned up in the human organism completely. Von Fellenberg,[1] of the Swiss Department of Health, has accordingly been able to demonstrate an output of methyl alcohol, in minute yet measurable traces, varying with the nature of the diet. The range was from inappreciable quantities, when pectin-free diets were consumed, to seven milligrams *or more* a day during a regimen including fruits. The intake was estimated at several hundred milligrams in the corresponding instances.

These seemingly insignificant figures indicating an almost complete destruction of the methyl alcohol from food sources would call for little comment were not further possibilities of latent danger suggested by the use of the distillates, such as the fruit brandies, containing both ethyl and methyl alcohol. A clinician of large experience with diseases of the eye has observed numerous cases of disturbances of vision in those parts of Switzerland in which fruit brandies, containing methyl alcohol as already indicated, are freely consumed.[1] The patients afflicted with retinitis or retrobulbar neuritis were commonly addicted to the use of these strong alcoholic beverages, rather than to wine or beer. It is scarcely justifiable to associate cause and effect on such meager and indirect evidence. Nevertheless the peculiar incidence of serious eye defects in the case of drinkers of *spirits known* to contain methyl *alcohol* derived from the sources of manufacture gives occasion for reflections on this subject.

Current Comment

A GOOD STYPTIC?

The control of hemorrhage frequently offers a problem of serious moment to the practitioner. The methods recommended and employed are diverse. Ordinary bleeding has a strong tendency to stop spontaneously with the formation of a clot, so that the benefit attributed to a drug that has been used as a hemostatic cannot easily be evaluated. As is the case with the user of popular "patent medicines," when return to normal conditions ensues, the credit is all too often given to the product employed rather than to physiologic functions that proceed despite the selected treatment. Evidence of this current confusion of cause and effect in relation to local hemostatics has been furnished in considerable detail by Hanzlik[1] of the Western Reserve University School of Medicine, Cleveland. He has tested the efficiency of reputed styptics under conditions of experimentation whereby the degree of control of superficial hemorrhage could be measured with accuracy. As a result it is stated in general that the local application of vasoconstrictor and astringent agents diminishes or arrests local hemorrhage, while vasodilator and irritating agents (without astringent action) increase local bleeding. The value of the newer thromboplastic agents of the kephalin or tissue extract type is considered as still uncertain. Epinephrin remains as a most efficient and desirable hemostatic agent. Its action is temporary, so that it should not be relied on for permanent hemostasis. Tyramin and pituitary extract also have given a good account of themselves, and unlike epinephrin they do not increase the bleeding later. The astringents as a class have proved variably effective, ferric chlorid and tannin standing highest in the list. The popular alum has been "disappointing," to quote Hanzlik. The vaunted cotarnin salts (stypticin and styptol), antipyrin and emetin were found to increase bleeding on local application. When systemic administration was employed, the effects on bleeding were usually parallel to the changes in blood pressure. Hawkins, investigating a number of styptics more than three quarters of a century ago, concluded:

---

[1] Von Fellenberg, T.: Ueber den Nachweis und die Bestimmung des Methylalkohols, sein Vorkommen in den verschiedenen Nahrungsmitteln und das Verhalten der methylalkoholhaltigen Nahrungsmittel im Organismus, Biochem. Ztschr. 85: 45, 1918.

> If, then, pressure for a few minutes on a wounded artery can permanently prevent hemorrhage, when that pressure is made with compresses dipped in various fluids, which neither produce contraction of artery nor facilitate coagulation, we are justified in concluding that if styptics are employed the cessation of the hemorrhage is to be ascribed principally, if not entirely, to the pressure or at all events in a minor degree to the action of the styptic.

The work of Hanzlik would indicate that our progress during the past century in this particular field has not been phenomenal or startling.

BACTERIA AND AMINO-ACIDS

In recent years the science of bacteriology has made noteworthy advances in the domain of the metabolism of the micro-organisms. It has developed that in many respects these low forms of life exhibit in their nutritive behaviors many resemblances to the higher animals which have been studied longer from the physiologic standpoint. Only a few years ago it was still believed that proteins undergo only slight digestive alterations prior to their absorption, whereas today it is generally accepted that the disintegration of these nitrogenous substances proceeds profoundly so that they leave the alimentary canal for the most part in the form of amino-acids. Protein metabolism in animals thus starts with these relatively simple products. Rettger and his collaborators at Yale University have demonstrated that native proteins like those of meat and egg are attacked only with difficulty by many types of bacteria. A preliminary cleavage of the protein molecule seems to be essential to the utilization of the nitrogenous fragments. More recently Robinson and Rettger[1] have furnished the added information that bacteria do not require proteins, even in minute quantities, to carry on their normal cultural development, but obtain their sustenance from less complex substances, as, for example, the amino-acids and perhaps some of the simpler polypeptids. The importance of this finding is more far reaching than appears on the surface. It suggests the possibility of accomplishing satisfactorily that which has been desired since the early days of bacteriology, namely, the growth of bacteria on synthetic mediums of known composition. Peptone — made in Germany — and indefinite infusions of complex character have all too long served as the sole mediums for culture work. It is a decided advantage to start with controllable and better defined compounds in the practical growth of bacteria and study of their products. These newe indications, together with the epoch-making recen contributions on the rôle of the hydrogen-ion concentration, and perhaps the suggestion of a part played by vitamins in bacterial growth, should help to pave the way for more rational procedures in enormously important fields of bacteriologic practice.

THE RESULT IN OHIO

In The Journal, last week,[1] attention was called to the position taken by the legislative committee of the Ohio State Medical Association on the bill exempting Christian scientists from the provisions of the medical practice act. It was pointed out that the medical profession of Ohio had done its full duty in showing the dangers to public health involved in the passage of the bill, and that the responsibility rested where it belonged, on the lay members of the legislature. The prompt reaction of these members to this definite placing of responsibility is shown by the defeat of the bill in the house last week by the decisive vote of eighty-three to twenty-two. No possible suspicion of self-interest can be attributed to the physicians, either as members of the state legislature or as representatives of the state association, who took such a position. The bill was defeated because the overwhelming majority of the members of the legislature were convinced that its passage was not in the interest of the public. It is safe to say that the influence and standing of the Ohio State Medical Society in the eyes of the state legislature and the public are far better than would have been the case if its members had participated aggressively in political activities against the measure.

---

[1] Ohio Finds a Better Way, Current Comment, J. A. M. A. 72: 497 (Feb. 15) 1918.

Open Air Classes.—Feb. 1, 1917, the New York City Department of Health officially took charge of the fresh air classes in the public schools. At that time there were eighty-four classes. According to *School Health News*, November, 1918, there are now 102, and failure to increase the number still further is due to the lack of available rooms, though the demand for additional classes is great. Types of children admitted to the classes comprise children exposed to tuberculosis at home, or in whose families there have been recent deaths from this disease; arrested or cured children; those suffering from malnutrition; those who become tired easily or show languor or fatigue before the end of the day; those suffering from nervous diseases, except chorea; those frequently absent on account of cold, bronchitis, etc.; those suffering from cardiac disease, who are recommended by their physicians as being proper for these classes. The class rooms are situated outdoors in parks, on ferry boats, on the roofs of schoolbuildings, or in rooms in schoolbuildings having specially arranged windows. These children are all fed at least once a day, and some have an extra luncheon morning and afternoon. The results show that most of them gain in weight, some improve in their scholarship, most of them are able to advance in their regular grades, and the general health improves.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending February 14, the Medical Corps contained 22,305 officers, a decrease from the previous week of 516. The Medical Reserve Corps contained 626 officers. The total number of medical officers discharged since the beginning of the war is 11,315.

Distinguished Service Awards

MARK M. DUFFY, Lieut., M. C., U. S. Army, 124th Field Artillery, Danville, Ill. For extraordinary heroism in action near Romagne, France, Nov. 1, 1918. Lieutenant Duffy displayed exceptional bravery in caring for the wounded and directing their evacuation under heavy shell fire. During the action he went under concentrated fire and rescued several wounded men.

ALFRED M. BERGSTEIN, Lieut., M. C., U. S. Army, 18th Infantry, Pottsville, Pa. For extraordinary heroism in action near Exermont, France, Oct. 8, 1918. Under heavy shell fire, Lieutenant Bergstein cared for the wounded although he had been severely wounded and was suffering great pain. He refused to be evacuated until all the wounded had been treated.

HIRAM E. ROSS, Major, M. C., U. S. Army, 18th Infantry, Danville, Ill. For extraordinary heroism in action near Villers-Tournelle, France, May 3-4, 1918. While under heavy bombardment, and working in an area saturated with gas, Major Ross showed extreme gallantry and efficiency, in caring for the more dangerously wounded, removing his mask at times during the attack to better ascertain the extent of the wounded. It was, while thus acting that he was severely gassed.

HONORABLE DISCHARGES, MEDICAL CORPS, U. S. ARMY

Note.—In the following list, L. signifies lieutenant; C., captain; M., major; L. C., lieutenant-colonel; Col., colonel, and B. G., brigadier-general.

ORDERS TO OFFICERS OF THE MEDICAL CORPS, U. S. ARMY

Alabama

To Fort Sill, Okla., base hospital, from Camp Devens, Lieut. M. J. HEATH, Pratt City.

Arkansas

The following order has been revoked: *To Walter Reed General Hospital* for instruction, from Camp Lee, Capt. R. C. KORY, Little Rock.

California

To Canal Zone, from Camp Kearney, Lieut. W. S. HARTFORD, Los Angeles.

To Carlisle, Pa., from Camp Grant, Major M. A. WILLIAMSON, Long Pine.

To Denver, Colo., from Camp Kearney, Lieut. J. B. LUCKIE, Pasadena; from Fort Winfield Scott, Capt. J. E. FAHY, Los Angeles.

To Fort Bliss, Texas, base hospital, from Camp Kearney, Lieut. F. J. BARNET, Los Angeles.

To Houston, Texas, Ellington Field, from Berkeley, Capt. B. F. SANDOW, Oakland.

To report to the commanding general, Western Department, from Camp Kearney, Major K. B. TURNER, Los Angeles.

To San Francisco, Calif., Letterman General hospital, from Camp Fremont, Capt. F. P. BOWEN, Los Angeles; from Camp Kearney, Lieut. T. J. NOLAN, San Francisco.

Colorado

To Denver, Colo., from Boston, Capt. C. G. McEACHERN, Denver.

To San Francisco, Calif., from Camp Dodge, Capt. J. D. WILSON, Ideal.

Connecticut

The following order has been revoked: *To Fort McHenry, Md.,* from Camp Dix, Major W. F. VERDI, New Haven.

Delaware

To New Haven, Conn., from Camp Dix, Capt. M. I. SAMUEL, Wilmington.

District of Columbia

The following order has been revoked: *To Rockefeller Institute,* for instruction, and on completion *to New York,* from Camp Meade, Capt. W. J. MANNING, Washington.

Georgia

To Camp Lee, Va., base hospital, from Camp Dix, Lieut. H. I. BATTEY, Atlanta.

Illinois

To Camp Devens, Mass., base hospital, from Walter Reed General Hospital, Capt. M. L. GALLAGHER, Chicago.

To Fort Oglethorpe, from Camp Dix, Major W. R. RAINEY, Salem.

To Fort Sheridan, Ill., from Camp McClellan, Capt. J. M. AXELSNO, Chicago; from Fort Des Moines, Capt. J. MYERS, Chicago.

To Hoboken, N. J., from Camp Custer, Capt. J. D. HAWKS, Cambridge.

To Philadelphia, Pa., from Dansville, Lieut. C. J. CHALLENGER, Chicago.

To report to the commanding general, Southern Department, *from* Austin, Major O. A. SUTTLE, Mount Vernon.

The following order has been revoked: *To Army Medical School, from Fort Oglethorpe,* Capt. J. W. HALL, Chicago.

Indiana

To Fort Sheridan, Ill., from Camp Gordon, Lieut. A. L. LOOP, Economy.

To Long Beach, N. Y., from Camp Pike, Lieut. H. G. HAMER, Indianapolis.

To Otisville, N. Y., from Camp Devens, Capt. E. A. CRULL, Fort Wayne.

To San Diego, Calif., Rockwell Field, from Vancouver, Capt. F. L. DARROW, East Haven.

To West Baden, Ind., from Camp Sheridan, Capt. H. L. MILLER, West Baden.

Iowa

To Fort Logan H. Roots, Ark., from Camp Logan, Capt. A. M. SHERMAN, Clarinda.

To Fort Snelling, Minn., from Otisville, Capt. W. L. HEARST, Cedar Falls.

To Hoboken, N. J., from Fort Des Moines, Lieut.-Col. A. von SCHRADER.

Kansas

To Chicago, Ill., from Fort Des Moines, Capt. C. M. FITZPATRICK, Salina.

Kentucky

To Boston, Mass., Northeastern Department, from Camp Devens, Major R. W. OGILVIE, Princeton.

Louisiana

To Fort Sam Houston, Texas, base hospital, from Camp Dix, Major U. MAES, New Orleans.

Maryland

The following order has been revoked: *To Camp Lee, Va.*, base hospital, from Camp Meade, Lieut. G. R. MICKLEWAIT, Baltimore.

Massachusetts

To Boston, Mass., from Camp Dix, Capt. F. E. LEWIS, Nantucket; from Camp Gordon, Lieut. A. A. CU[illegible] Reed General Hospital, Lieut. L. H. [illegible]

To Camp Lee, Va., from Camp M[illegible] Boston. Base hospital, from Camp [illegible], Springfield.

To East Norfolk, Mass., from Camp Dix, Lieut. W. OVERHOLSER, Westboro.

To Fort Riley, base hospital, from Camp Dix, Major C. C. BECKLEY, Lancaster.

To New Haven, Conn., from Camp Custer, Lieut. W. C. JENSEN, Worcester.

Michigan

To Army Medical School for instruction, from Camp Dix, Major F. C. KIDNER, Detroit.

To Detroit, Mich., from Camp Jackson, Capt. K. R. HARRIS, Detroit.

To Fort Sam Houston, Texas, base hospital, from Colonia, Major K. W. MAY, Detroit.

To Plattsburgh Barracks, N. Y., from Camp Dix, Major J. T. SAMPLE, Saginaw.

Minnesota

To Camp Meade, Md., base hospital, from Fort Oglethorpe, Lieut. H. W. STONE, Minneapolis.

Missouri

To Fort McPherson, Ga., from Camp Dix, Major S. I. SCHWAB, St. Louis.

To Fort Sheridan, Ill., from Camp Gordon, Capt. F. J. PFEFFER, St. Louis; from Newport News, Major F. W. BAILEY, St. Louis.

To Houston, Texas, Ellington Field, from Fort Crook, Lieut. O. R. ENGLEMANN, St. Louis.

To Rochester, Minn., Mayo Clinic, for instruction, from Rockefeller Institute, Lieut. W. S. CULPEPPER, Willow Springs.

Nebraska

To Camp Dodge, Iowa, as orthopedic surgeon, from Camp Zachary Taylor, Lieut. L. K. STRATE, Hastings. Base hospital, from Fort Des Moines, Lieut. W. E. WOLCOTT, Omaha.

To Carlisle, Pa., from Camp Lee, Lieut. C. M. HYLAND, Omaha.

To Walter Reed General Hospital, D. C., from Camp Travis, Lieut. J. D. McCARTHY, Omaha.

Nevada

To San Diego, Calif., Rockwell Field, from Vancouver, Lieut. D. W. BEDINGER, Ruth.

New Hampshire

To Camp Zachary Taylor, Ky., base hospital, from West Baden, Major A. F. WHEAT, Manchester.

New Jersey

To Carlisle, Pa., from Oteen, Major J. J. BRODERICK, Jersey City.

To Fort Douglas, Utah, from Camp Dix, Capt. A. F. GRAHAM, Paterson.

To Otisville, N. Y., from Fort Riley, Capt. H. S. SMITH, Newark.

To Walter Reed General Hospital, D. C., from New Haven, Capt. G. L. COOK, Penns Grove.

New York

To Camp Lee, Va., base hospital, from Army Medical School, Lieut. C. GOLDMAN, Brooklyn; from Camp Dix, Majors W. M. BRICKNER, New York; F. N. C. JERAULD, Niagara Falls.

To Camp Meade, Md., to examine the command for nervous and mental diseases from Camp Meade, Lieut. R. BOGAN, Brooklyn.

To Fort McPherson, Ga., from Camp Sevier, Lieut. S. L. SCIBETTA, Buffalo.

To Fort Warren, Mass., from Camp Dix, Major E. CUSSLER, New York.

To Hoboken, N. J., from Camp Dix, Capt. E. M. CONNELLY, New York; Lieut. M. J. TAYLOR, New York; from Camp Grant, Major W. A. MURPHY, New York.

To Jefferson Barracks, Mo., to examine the command for cardiovascular diseases, from Lakewood, Lieut. C. SHOOKHOFF, Brooklyn.

To Long Beach, N. Y., from Camp Dix, Lieut.-Col. J. J. MOORHEAD, New York.

To New York, Bellevue Hospital, as assistant instructor, from Washington, Lieut.-Col. W. J. ELSER, New York.

To Otisville, N. Y., from Camp McClellan, Capt. C. H. ERWAY, Elmira.

To report to the commanding general, Southeastern Department, from Camp Joseph E. Johnston, Capt. G. E. CLARK, Brooklyn.

To Rockefeller Institute for instruction in the treatment of infected wounds, and on completion *to his proper station*, from Camp Lee, Capt. M. I. BLANK, New York.

To Walter Reed General Hospital, D. C., from Camp Gordon, Lieut. L. F. KNOLL, Brooklyn.

Ohio

To Camp Sherman, Ohio, base hospital, from Camp MacArthur, Capt. W. E. RANZ, Youngstown.

To Camp Upton, N. Y., base hospital, from Fort McHenry, Lieut. J. F. WILLIAMS, Cincinnati.

To Fort Sheridan, Ill., from Camp Gordon, Capt. E. T. KNOOP, Cincinnati; Lieut. O. C. McDOWELL, Akron.

To Hoboken, N. J., from Camp Dix, Lieut. J. C. STAATS, Cincinnati.

Oklahoma

To San Francisco, Calif., from Fort Riley, Lieut. J. D. ENFIELD, Tulsa.

Oregon

To Fort Sheridan, Ill., from Fort Riley, Lieut. K. H. MARTZLOFF, Portland.

To San Francisco, Calif., Lettermann General Hospital, from Camp Lee, Capt. C. E. SAUNDERS, Medford.

Pennsylvania

To Camp Abraham Eustis, Va., from Camp Lewis, Major H. TUCKER, Philadelphia.

To Camp Meade, Md., from Camp Dix, Lieut.-Col. W. J. TAYLOR, Philadelphia.

To Fort Sheridan, Ill., from Camp Lee, Capt. H. W. MORROW, Swissvale; from Fort Des Moines, Lieut. L. W. WRIGHT, Williamsport; from Fort Oglethorpe, Lieut. H. E. MASSY, Sharon.

To Fort Warren, Mass., from Camp Dix, Lieut. G. M. BOGAR, Shamokin; from New Haven, Lieut. J. G. SILVERMAN, Philadelphia.

To Hoboken, N. J., from Camp Upton, Lieut. M. S. KLECKNER, Allentown; from Mineola, Capt. H. A. GREAVES, Philadelphia.

To Oteen, N. C., from Camp Gordon, Capt. I. H. ALEXANDER, Pittsburgh.

To Philadelphia, Pa., from Camp Dix, Capt. W. B. CADWALADER, Philadelphia.

To Plattsburg Barracks, N. Y., from Camp Dix, Major C. H. SMITH, Uniontown.

To San Francisco, Calif., from Camp Custer, Lieut. J. A. LOGAN, Pittsburgh.

To West Baden, Ind., from Camp Gordon, Major W. S. NEWCOMET, Philadelphia.

Philippine Islands

To San Francisco, Calif., for instruction, from Philippine Department, Major E. J. FARFROW, Manila.

South Carolina

To San Francisco, Calif., from Camp Wadsworth, Major C. LeBARON.

South Dakota

To Fort Riley, base hospital, from Fort McHenry, Capt. W. O. LEACH, Huron.

Tennessee

To Fort McPherson, Ga., from Camp Dix, Capt. A. W. HARRIS, Nashville.

Texas

To Camp Bowie, Texas, to examine the command for nervous and mental disease, from Fort Logan, Lieut. D. C. BURKES, San Antonio.

To Camp Custer, Mich., base hospital, from Camp MacArthur, Lieut. W. S. LORIMER, Handley.

To Camp Gordon, Ga., base hospital, from Hot Springs, Lieut. J. S. TOMKIES, Dallas.

To Camp Pike, Ark., base hospital, from Camp Lewis, Major J. C. ALEXANDER, Fort Worth.

To Denver, Colo., from Vancouver Barracks, Lieut. C. R. GOWEN, Carlsbad.

To Fort Logan H. Roots, Ark., from Camp Logan, Lieut. L. B. BIBB, Paris.

To Fort Sam Houston, Texas, from Camp Meade, Lieut. J. H. HAMILTON, Jonesboro. Base hospital, from Camp Dix, *Capt. R. F.* MILLER, Brenham; *from* Camp Travis, Lieut. H. O. BROWN.

To Houston, Texas, Ellington Field, from Austin, Lieut. D. H. BROOK, Travis.

To San Diego, Calif., Rockwell Field, from Vancouver, Capt. E. J. BURNETT, San Antonio.

To San Francisco, Calif., from Camp Abraham Eustis, Lieut. E. H. INMON, Tahoka.

Utah

To Camp Gordon, Ga., base hospital, from Fort McPherson, Lieut. H. SWANBERG, Salt Lake City.

To Fort Douglas, Utah, from Camp MacArthur, Capt. J. J. GALLIGAN, Salt Lake City.

To Jefferson Barracks, Mo., from Camp Hancock, Lieut. G. W. GOINS, Toolle.

Vermont

To San Francisco, Calif., from Camp Abraham Eustis, Lieut. C. W. CUMMINGS.

Virginia

To Philadelphia, Pa., from Camp Pike, Lieut. J. O. BOYD, Roanoke.

Washington

To Fairfield, O., Wilbur Wright *Field*, from Vancouver Barracks, Lieut. E. I. G. REINARTZ.

To report to the commanding general, Western Department, from Camp Fremont, Major C. H. STEARNS, Fort Ward; from Camp Kearney, Major S. Q. ELMORE, Pasco.

To San Francisco, Calif., from Camp Bowie, Capt. J. A. MAPES, Seattle. Letterman General Hospital, from Camp Kearney, Lieut. C. S. PASCOE, Tacoma.

West Virginia

To Camp Upton, N. Y., base hospital, from Camp Dix, Capt. W. L. VAN SANT, Hinton.

Wisconsin

To Fort Logan H. Roots, Ark., from Camp Logan, Lieut. E. L. SCHROEDER, Shawano.

To Fort Porter, N. Y., from Camp Jackson, Capt. S. G. PAKE, Hayward.

To Fort Sheridan, Ill., from Fort Riley, Lieut. P. J. MERTEN, Milwaukee.

ORDERS TO OFFICERS OF THE UNITED STATES PUBLIC HEALTH SERVICE

Surg. DANA E. ROBINSON, relieved at Providence, R. I., and from temporary duty at Chillicothe, Ohio, proceed to Evansville, Ind., and assume charge of the marine hospital at that place.

Surg. H. G. EBERT, relieved at the Columbia River Quarantine Station and from temporary duty at Manhattan, Kan., proceed to Chillicothe, Ohio, for duty in extracantonment sanitation.

Passed Asst. Surg. PAUL PREBLE, relieved at Cincinnati, Ohio, and at Portsmouth, N. H., proceed to Philadelphia, Pa., for duty in the Division of Health and Sanitation, Emergency Fleet Corporation.

Passed Asst. Surg. W. F. DRAPER, proceed to Richmond and other places in Virginia for conference with *health authorities in the matter* of demonstrations of rural sanitation.

Passed Asst. Surg. W. M. JONES, relieved at the Reedy Island Quarantine Station, proceed to the marine hospital, St. Louis, Mo.

Asst. Surg. R. R. SPENCER, relieved from temporary duty at St. Louis, Mo., *on the arrival of P. A. Surg. W. M. JONES*, proceed to Washington, D. C., for duty in industrial hygiene.

Asst. Surg. M. F. HARALSON, proceed to Alexandria and Lake Charles, La., and necessary points in Texas and Arkansas for inspection of work of extracantonment sanitation.

Asst. Surg. J. F. MAHONEY, relieved at Fort Worth, Texas, proceed to the New Orleans Quarantine Station for duty.

Acting Asst. Surg. W. S. RITENOUR, relieved at Anniston, Ala., proceed to Raleigh, N. C., for duty in extracantonment sanitation.

Acting Asst. Surg. M. H. WATTERS, proceed to Macon, Ga., for temporary duty in extracantonment sanitation.

Constr. Engr. N. V. PERRY, proceed to the Boston Quarantine Station for inspection of construction now being carried on.

Scien. Asst. J. P. ANDERSON, relieved at Florence, Ala., proceed to Pensacola, Fla., for duty in extracantonment sanitation.

Scien. Asst. G. S. BOTE, relieved at Fayettsville, N. C., report to Raleigh, N. C., for duty in extracantonment sanitation.

Scien. Asst. W. H. PRICE, proceed to Boston, Mass., for conference on health matters.

Scien. Asst. SAM SAUNDERS, relieved at Raleigh, N. C., report to the Hygienic Laboratory for duty in the study of vaccine.

Scien. Asst. W. C. VERDERY, relieved at Anniston, Ala., proceed to Fayetteville, N. C., for duty in extracantonment sanitation.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

ALABAMA

Vaccination Urged.—Dr. Judson D. Dowling, health officer of Birmingham and Jefferson County, issued a statement, January 28, urging persons who have not been vaccinated to secure vaccination immediately. A number of smallpox cases have recently been reported, and precautionary measures are necessary to avoid a repetition of the epidemic of last year.

Personal.—Dr. Haickel A. Elkourie, Birmingham, has been commissioned major, M. C., U. S. Army, and assigned to duty with the First Alabama Battalion, U. S. National Guard.——Dr. Charles A. Mohr, formerly city health officer of Mobile, has been elected full-time health officer of Mobile County. Under the new system an assistant health officer is provided and departments of vital statistics, laboratory, communicable diseases, *epidemiology*, meat and milk inspection, and chief sanitation inspector are established.

Medical Society Objects to Changes.—At a meeting of the Jackson County Medical Society held in Birmingham, January 27, a resolution was unanimously adopted opposing the bill recently introduced into the Alabama State Legislature which it is claimed tears down the present health service and replaces it by a system of questionable merit, averring that if the legislature will furnish proper support to the state health officer, the health and interests of the people of the state will be better conserved than by a radical change in the system.

Public Health Activities Cease in Montgomery.—*Robert* Olesen, P. A. Surg., U. S. P. H. S., has been directed by the Surgeon-General to arrange health matters in Montgomery so as to enable the municipality to take charge of the work when the service withdraws, which is expected to be about May 1. The health needs of Montgomery and Montgomery County as summarized by Dr. Olesen are:

1. A reorganized health department with a full time health officer in charge.
2. Continuation of antimalarial operations.
3. Maintenance of box and can sanitary system.
4. Continuation of government venereal clinic.
5. Educational efforts in behalf of public health through lectures, newspapers and pamphlets.
6. System of medical inspection in schools.
7. From two to four visiting nurses.
8. Thorough antifly campaign.
9. Prevention of smallpox and typhoid.
10. Cleanliness in establishments handling food and drink.
11. Safe milk supply through pasteurization.

ARIZONA

Personal.—Dr. George P. Sampson, Winslow, has been appointed superintendent of health of Navajo County.——Dr. Charles A. Thomas, Tucson, has been elected a member of the board of directors of the Tucson National Bank.——Dr. Ricketts, Tucson, has been appointed a member of the board of regents of Arizona State University.

CALIFORNIA

Physician's Petition Denied.—Judge George A. Sturtevant, San Francisco, January 14, it said to have denied the petition of Fischer R. Gordon, for the restoration of his license to practice medicine, which was revoked, January 25, by the state board of health after a hearing on the charge of having performed an illegal operation.

Medical Bills Introduced.—At a meeting of the California Society for Mental Hygiene held in San Francisco, February 2, passage of bills to establish a psychopathic hospital, to create a department of psychology at the State Penitentiary and to open the State Hospital for the treatment of mild cases of derangement on temporary commitment for observation and diagnosis, were urged.

Personal.—Dr. William F. Gates, Oroville, has been appointed county physician of Butte County and Dr. Lewis L. Thompson, Gridley, has been reappointed health officer of the county.——In the case of Dr. Mary M. Kroetz, San Francisco, whose license was revoked on a charge of attempting to procure an illegal operation, a writ of review has been granted by Judge Sturtevant.

Physicians in Trouble.—In connection with the mail fraud cases recently investigated by the federal grand jury at Los Angeles, which formed the basis for the return of six indictments involving violation of the postal laws, and alleged willingness to perform criminal operations, the following physicians are said to have been arrested: Drs. George W. Purcell, San Francisco; Augusta Stone, Los Angeles; Morris A. S. Franck, Los Angeles; George C. Somers, Los Angeles; Tom Shee Bin, Los Angeles, and Harry S. Walters, San Luis Obispo.

Campaign Against Venereal Diseases.—The machinery of the state board of health in its campaign against venereal diseases is now in operation in large parts of the state. Dr. Lewis Mickelson, San Francisco, head of the bureau of social hygiene of the state board of health is in charge of the work. Free clinics have already been established in ten of the principal cities of the state, and hospital clinics for venereal diseases will be equipped in many of the larger cities. Many of these clinics are open in the evening to accommodate persons employed during the day. Local health officers are empowered to isolate all persons deemed a menace to the public health.

Colloquia to Be Resumed.—The San Francisco Hospital Colloquia, both surgical and medical, have been resumed in the amphitheater at the San Francisco Hospital. The surgical colloquia commenced February 6 at 9 a. m., and the medical colloquia, February 7 at 9 a. m., and are to be continued thereafter weekly on Thursday and Friday mornings. These colloquia are open to all medical men and programs will be sent weekly, in advance, to all those who register with Dr. William Ophüls, dean of Stanford University Medical School, and pay a registration fee of $1 to cover clerical expenses; but whether registered or not, all physicians are welcome.

CONNECTICUT

Personal.—Dr. Gould A. Shelton, Shelton, celebrated the fiftieth anniversary of his entrance into the medical profession, January 14, and on that day was the guest of honor at a dinner given by physicians of Derby, Ansonia, Shelton and Seymour.

License Revoked.—An official report states that, Sept. 13, 1918, the state department of health of Connecticut revoked the license of Dr. George A. Faber, Waterbury, on the ground that he had been convicted by the superior court of Connecticut.

Elections.—At the annual meeting of the New Haven Medical Association, Dr. Louis M. Gompertz was elected president; Dr. Robert E. Peck, vice president; Dr. Frank L. Phillips, recording secretary; Dr. Samuel J. Goldberg, financial secretary, and Dr. Frank H. Wheeler, treasurer.——At the annual meeting of the New Britain Medical Society, January 8, Dr. Edward J. Dray was elected president; Dr. Joseph Robinson, vice president, and Dr. Frederick J. Mann, secretary-treasurer.

DISTRICT OF COLUMBIA

Personal.—Dr. Joseph A. Murphy has resumed his duties as chief medical and sanitary inspector of public schools.——Dr. and Mrs. W. Earl Clark, who have been for nearly two years working in the American Ambulance, Neuilly, France, have returned home.

Changes in Teaching Staff of Medical Department, Georgetown University.—Dr. J. Thomas Kelley has been appointed professor of gynecology, succeeding Dr. Isaac S. Stone, who becomes professor emeritus of that chair. Dr. C. R. Dufour has been made professor emeritus of diseases of the eye and ear. Drs. J. M. Moser and John A. Foote have been appointed associate professors of pediatrics.

New Assistant Health Officers for District of Columbia.—The post of assistant health officer which has been vacant since the promotion of Dr. W. C. Fowler to succeed Dr. W. C. Woodward as health officer has been filled by the appointment of Dr. John Paul Frey, a graduate of George Washington University, 1910, and recently on the scientific staff of the National Vaccine and Antitoxine Institute.

GEORGIA

Typhoid Vaccine Ready.—Dr. Marvin F. Haygood, La Grange, head of the department of epidemiology of the state board of health, announces that sufficient typhoid vaccine for 15,000 persons is now ready for shipment wherever wanted in the state.

New Departments of State Board.—Two new departments of the state board of health were inaugurated, January 1. A bureau of vital statistics in charge of Dr. W. A. Harris, formerly in charge of the vital statistics of Texas, and a division of epidemiology in charge of Dr. Marvin F. Haygood, La Grange.

New Officers.—Fulton County Medical Society at its annual meeting elected the following officers: president, Dr. Elmore C. Thrash; vice president, Dr. Walter B. Emery; secretary-treasurer, Dr. Elisha P. Merrit, reelected, and censor, Dr. Marion T. Benson. At the installation ceremonies, January 2, the society decided to appoint a committee to wait on the attorney-general and governor of the state and ask them to aid in ridding the state of unlicensed practitioners and quack physicians.

Healthology.—The first issue of "Healthology," the bulletin of the Georgia State Board of Health, appeared, January 15. It is edited by Ray C. Werner, assisted by Dr. Thomas F. Abercrombie, Atlanta, secretary of the state board of health. The chief articles in the first issue are "Result of Three Years of Active Public Health Administration in Floyd County," "Unfortunate Small Towns," "Checking Up on Tuberculosis" and "Physical Training and Examination of Schoolchildren."

IDAHO

Sterilization of Unfit.—Dr. D'Orr Poynter, superintendent of the Idaho State Sanitarium, Nampa, in the first annual reports of the board of trustees of the institution, was that the Idaho Legislature pass a eugenic law authorizing the sterilization of mentally and socially unfit persons.

New Officers.—At the annual meeting of the Bonner County Medical Society the following officers were elected: president, Dr. Charles P. Stackhouse, Sandpoint; vice president, Dr. A. L. Salmon, Clark's Fork, and secretary-treasurer, Dr. Floyd G. Wendle, Sand Point.

ILLINOIS

Personal.—Norval H. Pierce and Channing W. Barrett, majors, M. C., U. S. Army, both of Chicago, returned from abroad, February 17.——Dr. William Allen Pusey, Chicago, has been appointed consultant to the division of public hygiene of the state department of public health.——Dr. A. E. Owens, Princeton, has been elected president of the Bureau County Tuberculosis Association.——Dr. Rachelle S. Yarros, chairman of the subcouncil of the women's committee of the State Council of Defense, has been appointed supervisor of education for women.

MARYLAND

Hopkins Hospital Unit in the United States.—Members of the Johns Hopkins Base Hospital Unit arrived at Hoboken, February 15, aboard the *Finland*. Twenty-seven officers and 135 enlisted men under command of Major Richard F. Kieffer of Hagerstown comprised the unit which is now quartered at Camp Merritt, N. J., awaiting orders.

Addition to Frederick City Hospital.—At a meeting of the managers of the City Hospital of Frederick, a committee was appointed to solicit funds for the erection of a building adjoining the hospital for the treatment of contagious diseases. The need of an isolated department was made manifest during the recent epidemic of influenza. Because of the danger to other patients, no influenza cases were received at the hospital.

Library Building for the Johns Hopkins Hospital.—Plans, subject to change, have been drawn for a proposed new building on the grounds of the Johns Hopkins Hospital which will house the medical library of the hospital and the surgical histories of patients who have been treated there, and will also contain an auditorium, with subsidiary rooms for religious and philanthropic work. The new library will be built in honor of Dr. Henry M. Hurd, Baltimore, who for many years was superintendent of the hospital. The structure, according to present ideas, will cost $100,000 and will have a frontage of 100 feet on Wolfe Street, directly in the rear of the Administration Building. It will have a depth of 142 feet in the hospital grounds, its front three stories high, the building being of red brick and limestone, in harmony with the other buildings. A donation of $50,000 and one of $30,000 toward the structure have been made and it is thought that the remainder of the sum will be forthcoming.

Scarlet Fever on Increase.—A warning against scarlet fever has been sounded by the health department of Baltimore city. During the past week, 72 new cases were reported, while but 11 cases were in the city a year ago. The spread of the disease is largely the fault of parents, who fail to summon physicians in time and do not properly observe their children when they complain of symptoms which point to the disease. The cases have been mild in character and while the case rate has been high, there was but one death from the disease in a total of 364 fatalities, from all causes. Bronchopneumonia led all diseases in the number of deaths, the total from this disease being 47. There were 43 deaths from influenza, 36 from lobar pneumonia, 40 from heart disease, 29 from Bright's disease, and 26 from diseases of early infancy. Other diseases were fatal in the following number of cases: tuberculosis, 35; cancer, 9; apoplexy, 22; epidemic meningitis, 1; typhoid fever, 1; whooping cough, 4; diphtheria, 4. Births for the week aggregated 296. Three hundred and sixty-five new cases of influenza were reported for the week ending February 7. Sixty-four new cases of bronchopneumonia and 35 new cases of lobar pneumonia were reported for the week.

Personal.—Dr. John T. Geraghty, Baltimore, who was operated on at the Johns Hopkins Hospital for appendicitis, is convalescing, and will shortly return to his home in Guilford.——Capt. Hugh W. Brent, Baltimore, of the University of Maryland Base Hospital Unit has arrived in New York on the *Stockholm*. Captain Brent has been overseas for about a year and was stationed for a time at the Queen's Hospital, London, later joining his unit in France.——Major J. Albert Chatard, Baltimore, has sailed from Brest for the United States. He enlisted in the Medical Corps, July 1, 1917, and sailed for France as chief medical officer of Base Hospital No. 78. His headquarters while overseas have been for the most part at Toul.——Capt. George L. Stickney, Twenty-Sixth Infantry of the First Division, has returned from France and after a short furlough, reported at Camp Dix, N. J., to await further orders. He first served with the British, and in the autumn of 1917 joined the American Expeditionary Forces at Toul.——Capt. G. Hampton Richards, mayor of Port Deposit and physician to Tome Institute, who has been in France with the British and American Expeditionary Forces for more than seventeen months, has returned and is now stationed at Camp Dix awaiting discharge.——Lieut. David Silberman, Baltimore, has returned from overseas where he served eight months with the Eighty-Second Division.——Dr. J. Horton Kelly, Still Pond, has been taken to the Baltimore Hospital for enucleation of an eye, injured several months ago.

MASSACHUSETTS

Personal.—Dr. Richard C. Cabot, Boston, has returned from abroad.——Dr. John W. Baird, professor of experiments and psychology in Clark University, Worcester, is reported to be critically ill in Johns Hopkins University hospital, Baltimore.

Asks Appropriation for Study of Influenza.—On recommendation of the trustees of the Boston City Hospital, the mayor has asked the city council for a special appropriation of $3,000 for the study and treatment of influenza; of this amount $1,000 is for equipment immediately needed and $300 a month for assistants and laboratory supplies.

Advisory Health Staff Appointed.—On suggestion of Health Commissioner Woodward, Mayor Peters has appointed the following medical advisory board for the health department of Boston: Drs. Richard M. Smith, John P. Treanor, Anna G. Richardson, Edward J. Denning, J. Dellinger Barney, David L. Edsall, James J. Minot, Harry Linenthal, Henry M. Pollock, Horace E. Bragdon and John Bapst Blake.

MICHIGAN

Personal.—Dr. Mabel E. Elliott, Benton Harbor, has started for Asia Minor.——Dr. Ralph F. Miller has been appointed city physician of Adrian.

Reorganization of State Board of Health Proposed.—Franklin Moore, St. Clair, has introduced a bill into the state legislature providing for the reorganization of the state board of health by requiring the appointment of a state health commissioner of the state board of health, and an advisory council of five physicians who will have charge of the health program throughout the state. The bill provides that the health commissioner shall be appointed for a term of six years and shall receive a salary of $6,000 annually, that he must be a registered practitioner and must have been in active practice for five years. The chief deputy will receive a salary of $3,000, and at least three of the five members of the advisory council must be qualified physicians and will receive actual expenses and $10 a day while attending meetings of the state council.

MISSOURI

Annual Banquet of Society.—At the annual banquet of the Buchanan County Medical Society at St. Louis, Dr. Daniel Morton acted as toastmaster; the retiring president gave his annual address and introduced the incoming president; an address was given by Rev. C. Hely Moloney, and returned medical officers of the society narrated their experiences in service.

New Officers.—At the annual meeting of the Green County Medical Society at Springfield, Dr. Joseph W. Love, for several years recording secretary, was elected president; Dr. Eugene C. Roseberry, vice president; Dr. Thomas O. Klingner, secretary (reelected for the tenth consecutive term), and Dr. Walter E. Handley, treasurer, all of Springfield.——William O. Owen, colonel, M. C., U. S. Army, director of the Army Medical Museum, delivered an address on "War Surgery," illustrated by moving pictures, before the St. Louis Medical Society, January 11.

NEW YORK

Hearing on Twomey Bill.—A hearing on the Twomey bill, which would transfer the powers of the department of narcotic drug control to the state department of health, was held, February 11. It is understood that Governor Smith sent a special message to the senate public health committee urging that this be done.

Personal.—Dr. Jacob Goldberg, Buffalo, has been appointed a member of the state public health council.——Dr. Charles W. Pilgrim has been elected chairman of the section on mental hygiene and medical advice of the state conference of charities and corrections.——Dr. Frederick Peterson, New York City, has been renominated as superintendent of the Craig Colony for Epileptics, Sonyea.

Association Changes Name.—At the annual meeting of the Rochester Tuberculosis Committee, held February 6, the name of the organization was changed to the Rochester Tuberculosis Association. The following officers were elected: chairman, Dr. Howard L. Prince, member of the executive committee, Drs. Henry T. Williams and Joseph Roby. The address of the evening was delivered by Dr. Donald B. Armstrong, executive officer of the community health demonstration, Framingham, Mass.

State Hospital Commission Makes Recommendations.—The building of a new psychopathic hospital in New York City has been recommended to the legislature by the state hospital commission in its annual report. Enlargement of the Creedmoor branches of the Brooklyn Hospital are also recommended. The proposed psychopathic hospital for New York City is for preliminary treatment and research work in New York City and the need of such an institution is being stressed as most urgent. The report shows that during the year 1918 the state spent $10,484,000 for its insane, the per capita cost per diem was only 72 cents. A total of 45,136 were treated in thirteen civil hospitals, and 37,352 patients are now being cared for. Of those discharged 3,452 were benefited by treatment and 1,637 cured. A marked decrease of insanity from alcoholic causes was noted. At the close of the fiscal year fifty-two state hospital physicians were on military duty.

Postgraduate Course in Infectious Diseases and Public Health.—Arrangements have just been perfected by which a new course in infectious diseases and public health will be given under the joint direction of the Albany Medical College and the New York State Department of Health, to start, March 5, and to be open both to physicians and health officers, but with no connection with undergraduate instruction. The course will be under the general supervision of Dr. Charles C. Duryee, sanitary supervisor, state department of health, Albany, to whom all correspondence regarding the course should be addressed. The fee for the course is to be $25, payable in advance or in monthly instalments if desired. Those who have completed any of the various courses of instruction for health officers, either at Albany or elsewhere, are invited to attend the course at a nominal fee of $5. Attendance of one day weekly during March and April, and one and a half days during May and the first two weeks in June will be required. On completion of the course and a satisfactory examination a certificate will be issued.

New York City

Harvey Society Lecture.—The fourth lecture of the Harvey Society series will be developed at the New York Academy of Medicine, March 1, at 8:30 p. m., by Dr. Frederick S. Lee, on "Industrial Fatigue."

Personal.—Dr. William E. Lippold, Brooklyn, is reported to be seriously ill with septicemia due to an operation wound.——Dr. Herman Seidler, Brooklyn, charged with driving his automobile across Manhattan Bridge at the rate of 30 miles an hour, is reported to have been fined $100 and sentenced to ten days' imprisonment in the city prison. This is his sixth conviction for this offense.——Dr. S. Dana Hubbard has been placed in charge of the division of industrial hygiene of the department of health.

Free Clinic for Speech Defects.—The first free medical clinic devoted solely to the treatment of defective voice and speech defects has been opened at 142 East Thirty-Seventh Street. This clinic has the following definite objects: To cure all forms of speech and voice disorders such as stuttering, lisping, stammering, nasality, cleft palate speech, etc.; to take care of defective teeth, mouth or jaw conditions when these are the cause of defective speech; to take care of nervous and mental conditions when they are causative or associated with defective speech and to reeducate patients to overcome their faulty voice or speech habits. The clinic will also maintain a central information bureau and clearing house for speech and voice disorders. One of the special features of the clinic are the evening classes. Dr. James Sounett Greene is the medical director.

OHIO

Profiteering Charges Inquiry.—On invitation of the Cleveland Academy of Medicine, the state medical board agreed to conduct an investigation in Cleveland, beginning January 23, as many complaints of profiteering among physicians had been made to the acting health commissioner of Cleveland. The attorney-general, who was consulted in the matter, ruled that the board was without authority to make such examination.

Continues Practice Although Unlicensed.—Statement made by Levi W. Hunt, Toledo, a chiropractor, before a joint health committee of the general assembly at Columbus, February 6, apparently indicates that this individual's license to practice has been twice revoked, first on a charge of gross immorality, and second for objectionable advertising, but nevertheless he continues to practice. The committee stated that investigators will be sent to Toledo and that Hunt will be prosecuted on a charge of practicing medicine without a license.

Personal.—Dr. Louis Kahn, health officer of Columbus, has resigned, his resignation to take effect, February 15.——Dr. Pinckney D. Shriner has been appointed president of the board of health of Columbus.——Drs. Wells Teachnor, Ira B. Hamblin and Oscar H. Sellenings have been appointed members of the board of health of Columbus.——Dr. Daniel B. Spitler, Hoytville, has been appointed coroner of Wood County.——Dr Franklin D. Sickles, Fredericktown, suffered amputation of his right leg at the knee, January 23.——Claud C. Craig, Urbana, has been appointed health department head at the work of the Victor Rubber Company, Springfield.

PENNSYLVANIA

Philadelphia

Personal.—Lieut. Penn-Gaskell Skillern, Jr., senior medical officer aboard the *U. S. S. Orizaba,* has been recommended the second time for devotion to service.——Dr. Jacob J. Schweller has been appointed clinical assistant physician, board of health.——Dr. Peter Moylan has been appointed a member of the state board of public charities to succeed Mrs. Elizabeth Thaw.

Hospital to Open Soon.—The Harriman Hospital, which was recently built and equipped at a cost of approximately $100,000, will be formally opened for reception of patients. The hospital will be conducted not only for the benefit of the employees of the Merchant Shipbuilding Corporation at Harriman, but for the treatment of cases from Bristol, Newtown, Langhorne, Hulmeville and other surrounding towns.

Medico-Chirurgical Reopened.—The University of Pennsylvania Graduate School of Medicine reopened the Medico-Chirurgical Hospital on Saturday, February 15, when Philadelphia physicians were invited to a private inspection of the plant. The hospital will be employed for general hospital work and has been equipped throughout with new medical and surgical instruments of the most recent development. There will be departments of medicine, surgery and obstetrics. Although it is to be used as a general hospital it is intended to become a center of instruction and clinical work for graduate students of the University of Pennsylvania. The department of medicine is in charge of Dr. James M. Anders; surgery, Dr. Francis A. Mantz, and obstetrics, Dr. William R. Nicholson. The hospital has more than 100 beds.

TENNESSEE

Personal.—James L. Andrews has taken up his former duties as superintendent of the Memphis Health Department. ——Dr. Newman Taylor has resumed his work as secretary of the health department of Memphis, and Dr. Hiram B. Jacobson, who has been acting as secretary, has taken up again his work as inspector of schoolchildren.

Hospital Notes.—A contract was let, February 11, for additional improvements to the main building of the Baird-Dulaney Hospital, formerly the Hosmer Hospital, Dyersburg, to cost about $50,000. Application has been made and approved by the legislature of the state to increase the capital stock of the institution from $25,000 to $75,000.——The Nashville Protestant Hospital offered a deed of trust, January 20, to cover the loan of $30,000 secured for the purpose of paying for its real estate and for the equipment of a new ward, and for the improvement and extension of its hospital facilities.——Arrangements are being made for repair work on the Lincoln Memorial Hospital, Knoxville, which was damaged by fire, Dec. 6, 1918. The repairs will cost from $6,000 to $7,000.——At the annual meeting of the Baptist Memorial Hospital, Memphis, it was reported that during the year 5,787 patients had been cared for, 1,000 of whom were free patients. With the completion of the new wing the hospital will have a capacity of 500 patients. It is expected that the new wing will be ready for occupancy this month.——The Government Free Trachoma Hospital, Tazewell, which has been closed for several weeks, was reopened, January 14.——The McNabb Sanitarium for the Treatment of Noncontagious and Nonsurgical Diseases, Knoxville, has been opened, and will accommodate ten patients.

TEXAS

Personal.—Dr. Beverly F. Young, San Antonio, was reelected superintendent of the Southwestern Insane Asylum, February 6.——Dr. Charles W. Goddard, Holland, has been appointed city health officer and president of the state board of health, to succeed Dr. William B. Collins, Austin.

Nominations for State Board.—Governor Hobby, January 29, sent the following nominations for the state board of medical inspectors: Dr. William C. Swain, Dallas County; Dr. Cabel O. Terrell, Eastland County; David Berry, Bexar County; S. L. Maye, Bell County; R. Y. Lacy, Camp County; D. W. Davis, Jefferson County; D. S. Harris, Harris County; Thomas J. Crowe, Dallas County; Horace C. Marrow, Travis County, and Marquis E. Daniel, Fannin County.

Public Health Commission Appointed.—The Texas Public Health Commission, appointed by the governor to investigate health conditions in Texas and report its findings, is composed of Dr. Otto C. Ahlers, Sherman, representing the Texas Town and City Planning Association, chairman; Mr. Charles Saville, Dallas, of the State Council of Defense, Committee on Sanitation and Medicine, vice chairman; Mr. D. E. Breed, Austin, representing the Texas Public Health Association, secretary; Dr. Platt W. Covington, Austin, representing the International Health Board; Dr. Selwyn P. Rice, Marlin, representing the State Medical Association of Texas; Mr. R. C. Bedicheck, Austin, representing the University of Texas, Extension Unit; Dr. W. A. Davis, Jr., Austin, representing the state board of health; Miss Anne Webb Blanton, Austin, representing the department of education; Dr. R. C. Derivaux, P. S. Surg., U. S. P. H. S., New Orleans; Mr. Elmer Scott, Dallas, representing the Texas Society Hygiene Association, and Mr. A. A. Long, representing the Texas League of Municipalities.

WISCONSIN

Elections.—Outagamie County Medical Society at Appleton, January 28, president, Dr. Manly J. Sandborn, Appleton, and secretary-treasurer, Dr. George T. Hegner, Appleton.——Eau Claire County Medical Society, at Eau Claire, January 27, president, Dr. E. M. Seizer; vice president, Dr. William O. Seemann, Eau Claire; secretary, Dr. Roy E. Mitchell, Eau Claire.——Brown-Kewaunee County Medical Society, at Green Bay, January 21, president, Donne F. Gosin, Lieut., M. C., U. S. Army, Green Bay; vice president, Dr. Nobert M. Kersten, DePere, and secretary-treasurer, Dr. Edwin S. McNevins, Green Bay.

Personal.—Drs. Edward S. Hayes, Eau Claire, and William F. Whyte, Watertown, have been appointed members of the state board of health and vital statistics.——Dr. Valentine A. Gudex, Milwaukee, has been appointed deputy state health officer in charge of the fourth district, with headquarters at Eau Claire.——Dr. L. Rock Sleyster, superintendent of the State Hospital for the Criminal Insane, Waupun, has resigned to become superintendent of the Dr. Richard Dewey Sanitarium, Wauwatosa.——Dr. John M. Dodd has been reelected president of the Ashland General Hospital Association.——In the damage suit for $20,000 brought by Clarence Van Wegner, New Holstein, against Dr. William G. Doern, Milwaukee, in which the jury returned a verdict for $3,600 for the plantiff, the verdict was set aside by Circuit Judge Gregory, January 22, who stated that the evidence submitted was sufficient to exonerate the physician.

CANADA

Influenza Kills Indians.—According to the official figure of Dr. Orton I. Grain, Winnipeg, chief medical officer for the Federal Government of Indian affairs, approximately 750 deaths from influenza have occurred among the 14,179 Indians of Manitoba.

University News.—The medical building of the University of Toronto is to be enlarged by a new addition.——The Carnegie Corporation of New York has voted a grant of a half million dollars to Queen's University, Kingston, Ont. This grant is related to that in the will of Dr. James Douglas, New York, and is conditional on raising an additional $500,000.

Pensions in Canada.—A new arrangement has been established in connection with pensions to soldiers in Canada. District officers of the different military districts will now not only examine the soldier but will estimate his percentage of disability, so that the work will be completed by the medical board which examines the soldier. Final decision will, however, rest with the central office at Ottawa.

Hospital News.—A new undenominational hospital is to be built in connection with St. Michael's parish, Belleville, Ont. ——A new federal sanatorium for Ontario soldiers is to be established in that province by the Dominion government. The province will shortly select the site. It will be for soldiers suffering with tuberculosis. Half the cost will be borne by the province of Ontario, and half by the Dominion. Three hundred thousand dollars is to be spent on the work.

Personal.—Lieut.-Col. William J. O. Malloch, who has just returned to Toronto from four years' service overseas, is ill with pneumonia. Dr. Malloch went over with the University of Toronto Base Hospital in 1915, was at Saloniki, and latterly has been chief surgeon at the Basingstoke Military Hospital.——Dr. William J. McCollum, Toronto, was taken ill on a holiday visit to Florida.——Lieut.-Col. Robert B. Wilson, roentgen-ray expert, Montreal, is at present doing military work in Toronto.——Lieut.-Col. Hardy of the Toronto Military Base Hospital has been appointed officer in command at the New Rosedale Military Hospital.

GENERAL

International Meeting of Obstetricians and Gynecologists.—Preparations have already been begun for the international meeting of gynecologists and obstetricians which is to be held in New York City, Sept. 14, 15, 16 and 17, 1920. Dr. J. Riddle Goffe of New York is the president.

Federation of Associations for Cripples.—The *American Journal of Care for Cripples,* a special periodical in English on provision for the disabled, becomes a monthly with its January issue, according to announcement by its editor, Douglas C. McMurtrie. The journal is now entering on its eighth volume. This periodical will contain in the future the studies, translations, and abstracts produced by the research department of the Red Cross Institute for Crippled and Disabled Men, which material has hitherto appeared in a special series of publications. The Journal also continues as the official organ of the Federation of Associations for Cripples.

W. W. Palmer Succeeds J. H. Long on the Council on Pharmacy and Chemistry.—At the recent meeting of the board of trustees, C. L. Alsberg, chief of the Bureau of Chemistry, U. S. Department of Agriculture; John Howland, professor of pediatrics, Johns Hopkins University Department of Medicine, and Henry Kraemer, professor of pharmacognosy, University of Michigan, College of Pharmacy, were reappointed to serve on the Council on Pharmacy and Chemistry for a further period of five years. The trustees appointed W. W. Palmer, associate professor of medicine at the College of Physicians and Surgeons of Columbia University, to fill the vacancy caused by the death of Prof. J. H. Long, who had been a member of the council since its organization. Walter Walker Palmer took his B.S. at Amherst in 1905; received his M.D. from Harvard Medical School in 1910; was a Fellow of Medicine at Harvard from 1915 to 1916, serving under Dr. David L. Edsall, former member of the Council on Pharmacy and Chemistry; was assistant professor of medicine at Cornell University Medical College in 1917, and associate professor of medicine at the College of Physicians and Surgeons of Columbia University in 1918. Dr. Palmer has also been actively engaged in various biologic researches at the Rockefeller Institute. Among his publications are: Significance of Urinary Acidity in Nephritis, Paroxysmal Edema, Absorption of Protein and Fat After Resection of Half the Small Intestine, Basal Metabolism and Creatinine Elimination, and Factors of Acid Secretion. He and co-workers at the Rockefeller Institute have also published a large number of articles on acidosis and its relation to diabetes. "The Colormetric Determination of Hemoglobin" by Palmer is officially recognized for use in U. S. Army Hospital Laboratories.

FOREIGN

Vaccination in Africa.—A Spanish exchange states that the Sultan of Tangier has decreed that no one can enter the French zone without presentation of a vaccination certificate.

Deaths in the Profession Abroad.—Dr. **H. G. Plimmer,** professor of comparative pathology in the Imperial College of Science, London, author of numerous works on tropical diseases, microscopic findings, Plimmer's bodies, etc., aged 61. ——Dr. **I. C. L. Holm,** the leading spirit in the development of the sanatorium system in Norway, aged 73.

Tuberculosis Among Belgian Refugees in the Netherlands.—The *Nederlandsch Tijdschrift* relates that among 23,791 Belgians living scattered in 320 different communities about 3 per thousand are *tuberculous.* In the refugee camps, however, the proportion is much higher, up to 11.8 per thousand among the 14,844 refugees crowded in four refugee camps. Only in one of the camps had hospital provision been made for them at that time.

Work of Medical Students During the Epidemic.—The *Siglo Medico* of Madrid relates that the municipal authorities of Ciudad Real recently distributed diplomas to the medical students of the town expressing the grateful appreciation of the public for the assistance they rendered during the epidemic of influenza. The ceremony was presided over by the governor, and at its close a banquet was tendered the students by the Junta de Sanidad.

Scarcity of Drugs in Norway.—The *Norsk Magazin for Lægevidenskaben* recently published an official communication to the effect that owing to the scarcity of hypophosphis calcicus, the syrupus sacchari is to be used in its place in compounding the syrupus pectoralis of the Pharmacopeia. Extreme economy in the use of camphor is also ordered, reserving it for strictly internal uses. A further order specifies that substances must not be used in sterilizing rooms which destroy the paint, as the supply of linseed oil is so low that it must be saved for strictly necessary painting, and existing paint must be spared from damage. It is stated that paint can be washed without harm, with proper care, and effectually sterilized by using formaldehyd-green soap, cresol soap or phenol-green soap, for the soap suds. Crude potassium permanganate is not to be obtained in the market, and the purified costs 20 crowns per kilo, a prohibitive price for its use in sterilization of rooms.

The New Premier of Spain a Physician and Medical Editor.—The profession in Spain is rejoicing over the appointment of Dr. Amalio Gimeno y Cabañas to be ministro de la Gobernacion, the premier of the realm. He heads the large editorial staff of the *Siglo Medico* of which Cortezo—who has also been in the cabinet—is director. Dr. Gimeno is professor of general pathology at the University of Madrid, and has long been a prominent figure in contemporaneous medical science in Spain. During his vacations he found relaxation in assuming charge of a spa, as director of a *balneario.* The choice of Dr. Gimeno is hailed by the profession in Spain as an augury of better things in public health matters and as an honor to the profession. No physician has been appointed premier in Spain for a long time, not since the days of Dr. N. M. Rivero. In a recent interview, Dr. Gimeno stated that he had already drawn up an outline for certain measures to hasten the time when Spain will rank in public health matters with the peoples now taking the lead in progress. The measures outlined for presentation to the cabinet include motherhood allowances, pure food legislation, hygiene for factories and shops, and protection for women and children. In talking with the king, he dropped the rôle of premier and, speaking only as a professor for forty years, urged the king to start a movement for a better equipped building for the medical school, to bring its quarters up to date and offer attractions to foreign students.

Medical Research in Australia.—The Walter and Eliza Hall Institute of Research in Pathology and Medicine has been established in Melbourne in connection with the Melbourne Hospital, through the generosity of the trustees of the Walter and Eliza Hall Fund. The institute is controlled by a board representing the trustees, the University of Melbourne and the Melbourne Hospital. A spacious building, including a basement and three stories, has been erected at a cost of over $60,000 in immediate connection with the pathologic department of the hospital. The hospital itself has recently been entirely rebuilt and now contains 350 beds. Applications for the offices of director and of first assistant of the institute are being invited through the agent-general for Victoria, Melbourne Place, Strand, London, from whom full information may be obtained. The director has the management of the institution; devotes his whole time to this work, is responsible for keeping research as the primary object of the institution, will give all assistance to the medical staff and other officers of the Melbourne Hospital in postmortem work and clinical pathology, will make arrangements for clinical instruction and laboratory instruction to medical students in postgraduate work, and provide or maintain the comforts of patients or others residing in, or who use the hospital. His term of service is five years and he is eligible for reappointment. His salary is $5,000 a year, payable monthly, and in addition, the board will procure an endowment insurance on the director's life, to be payable at the age of 60 or predecease, the annual premium for this insurance being $375. If the director comes from America, $625 will be allowed for travel expenses. Applicants should be between the ages of 25 and 35. All applications must be accompanied by original or certified copies of testimonials, schedule of experience, list of research work and photograph.

It is expected that the director will take duty, Oct. 1, 1919. The first assistant director shall be not over 35 years of age, and will be expected to devote his entire time to the work of the institute as directed by the board and under the instruction of the director. He will have the management of the institution in the absence of the director, will give such assistance as may be prescribed to the medical staff or other officers of the Melbourne Hospital in postmortem work and clinical pathology and bacteriology, and will take such part as may be prescribed in the instruction of medical students in laboratory work and in postgraduate instruction. He holds office for five years and is eligible for reappointment. His salary will be $3,000 a year, payable monthly.

SOUTH AND CENTRAL AMERICA, MEXICO AND WEST INDIES

Colombian Medical Congress.—The *Repertorio* announces that the Fourth National Medical Congress will convene at Tunja in August. The registration fee is $5 m/n which is to be forwarded to the secretary-treasurer, Dr. José del C. Cardenas, Bogotá, Colombia.

CORRECTION

Texas Appropriation.—The item under Texas News in The Journal of January 25, headed "Deficiency Appropriation for Tuberculosis Colony" was incorrect in that the appropriation of $20,000 was not allowed as a deficiency, but was added to the general appropriation bill now before the legislature and has been reported favorably but not yet passed. It is believed, however, that the bill will pass. This appropriation is to provide for furniture for two new dormitories with a capacity of 144 patients, making a total capacity of the institution of 325.

PARIS LETTER

Paris, Jan. 23, 1919.

Gas Gangrene

At a recent meeting of the Académie des Sciences, Dr. Charles Richet, professor of physiology in the Paris medical faculty, reported the results from the use of multivalent serum in the treatment of gas gangrene. This serum was obtained from horses that had been injected with the cultures of sixteen micro-organisms most commonly found in cases of gas gangrene. Some of these horses were also immunized against tetanus.

As a result of these injections, the general and local conditions of these patients improved rapidly; the pulse improved, urine secretion was increased, the characteristic facies disappeared, and the gas which had penetrated the tissues, and sometimes entered the thorax and abdomen, sometimes was absorbed in a few hours. Eighty-one cases were treated in this way, with sixty-nine cures and twelve deaths—the percentage of cures being 85.19. Four of the fatalities occurred among men who had survived the gas gangrene but died of some other affection, such as, tetanus, bronchopneumonia with purulent pleurisy, double pneumonia, etc. Therefore, the actual mortality from gas gangrene was only eight, a death rate of 9.87 per cent. Some of these patients were at the point of death at the time the serum was injected. A certain number, whose condition was recognized as being desperate, were cured by the serum injections. In several cases, where amputation or disarticulation was not done because of the enfeebled state of the patient or the extent of the gangrene, the limb was saved to the patient. The preventive and curative use of this serum is regarded as being an important aid to the surgical treatment of wounds infected by the bacteria ordinarily found in gas gangrene.

Compulsory Notification of Tuberculosis

The Conseil des ministres has authorized its president, the minister of the interior and the minister of finance, to present to the chamber of deputies a bill providing for the compulsory notification of open cases of pulmonary tuberculosis, as proposed by Dr. Louis Mourier, undersecretary of state for the Service de Santé militaire. This bill provides also for the free treatment and hospitalization of these persons and pecuniary support for the patient's family. Dr. Mourier called attention to the fact that measures of this kind have been in force during the war for the care of tuberculous soldiers. About 55,000 tuberculous soldiers have been cared for in the hospitals and dispensaries, and the regulations now in force must be extended because there are at this time about 500,000 tuberculous persons in France. It is estimated that it will cost 84 millions of francs to provide the needed establishments, and that the annual expenditure will amount to 100 millions ($20,000,000).

A Prehistoric Pathologic Specimen

Dr. Marcel Baudouin recently exhibited to the Académie de médecine a pathologic specimen that is probably about 12,000 years old. The specimen is an inferior maxilla of the neolithic period, which shows positive evidence of a fracture which healed spontaneously, and of a curious hypertrophy of the posterior surface of the bone. This bone was excavated during the recent work done on military defenses in the outskirts of Paris. It was buried under a dolmen.

Public Health and the Sanctity of the Home

Should the sanctity of the home preclude carrying out certain public health measures? The mayor of Toulouse informed the public that in view of the establishment of the "casier sanitaire des maisons," the sanitary record of the building, the employees of the Bureau d'hygiène would visit the houses to gather the data. All persons who refuse these agents admission lay themselves liable to prosecution. Several householders regarded this edict as a violation of the sanctity of the home, and have appealed to the Conseil d'Etat. That body decided, however, that the law gives the mayor the right to enter a home for health reasons as set forth in the law of Feb. 15, 1902, regarding the protection of the public health. The exercise of these powers is practically impossible in many cases without an examination of the premises. The appeal of the proprietors was denied.

Instruments for Physicians of Devastated Regions

The Conseil général of the Association des médecins de France unanimously adopted a resolution asking that the undersecretary of state for the Service de Santé militaire consider the transfer or assignment and sale to the physicians of the devastated regions, whether in service or not, of the instruments and apparatus made otherwise useless by the demobilization of the various sanitary formations and supply depots. In the case of physicians entitled to war damages (*dommages de guerre*) the price of the instruments will be deducted from the sums due the purchaser.

Child Welfare Work

A conference held at Lyon, attended by Dr. Lucas, director of the children's bureau of the American Red Cross, and a French committee consisting of physicians and laywomen interested in child welfare in Lyons, decided to transfer the work of the children's bureau to the French committee. The Lyons societies which have been interested more especially in children's welfare have amalgamated, in a way, so as to collaborate with the committee which succeeds the American bureau. The Holtzmann hospital will also be in charge of the Comité français.

Deaths

Dr. Paul Fabre of Commentry, département de l'Allier, died recently, aged 73. He had been a national corresponding member of the Académie de médecine since 1889, and a corresponding member of the Académie royale de médecine de Belgique. He was best known for his work in industrial hygiene. He was especially interested in the health of the miners, the sanitation of collieries and the effect of underground work on miners.

Dr. Lesieur, professor of pathology and general therapeutics in the Lyons medical faculty, died from an attack of influenza contracted while on furlough.

Dr. Albert Weil, chief of the electroradiologic laboratories of the Trousseau hospital, died in Paris from pulmonary congestion. He was the author of numerous works on therapeutics, among them a textbook, Eléments de radiologie, which was recently awarded the Itard prize.

Dr. Lucien Butte, president of the Société de médecine de Paris and of the Association centrale des médecins de France, assistant physician-in-chief to the prefecture of police, died, aged 63 years.

Personal

Dr. Georges Clemenceau was unanimously elected honorary president of the Société de médecine de Paris.

Medical Inspector-General Sieur has been made president of the Comité consultatif de santé de l'armée, replacing Dr. Février. . . . Dr. Astruc, *agrégé*, adjunct professor in the Ecole supérieure de pharmacie of Montpellier, has been made professor of galenical and industrial pharmacy, a new chair.

Association of Parisian Medical Students

In response to common demand and in order to afford their comrades in arms an opportunity of taking up intensively their medical studies, the medical section of the Association générale des étudiants de Paris has recently decided to open an information office. In this connection the association has endorsed the prewar program (including didactic and clinical conferences, notices of vacancies and aid in securing reinstatement in former positions), and the furtherance, with the authorities, of compensation claims. Some of these appeals have already been granted, in that the mobilized students have been allowed to return to their universities and have been permitted to resume their former studies with full credit.

American Physicians Receive Legion of Honor Decoration

At the suggestion of M. André Tardieu, commissioner general aux affaires de guerre franco-américaines, the following named Americans have been made officers of the Legion of Honor: Dr. Livingston Farrand, president of the University of Colorado and president of Rockefeller Tuberculosis Commission; Dr. Simon Flexner, professor of pathology in the Rockefeller Institute. Dr. Selskar Gunn and Dr. Alexander Miller, assistant to Dr. Farrand, have been made chevaliers of the Legion of Honor.

LONDON LETTER

London, Jan. 29, 1919.

The Interallied Fellowship of Medicine

The objects of the Interallied Fellowship of Medicine (described in previous letters to The Journal), as stated by the honorary secretary, Sir St. Clair Thomson, are: 1. The coordination of all the resources of medical interest throughout this country so as to make them readily available for demonstration and investigation. 2. Initiation of schemes of scientific entertainment. These would embrace the arranging of facilities for visits to, or courses of study in, the various clinics, laboratories, museums and other medical institutions; the regular attendance on any one particular service or course of lectures or demonstration, and in addition the preparation of specially arranged addresses, demonstrations or scientific visits. 3. Later on the fellowship would be actively helpful in collecting and distributing information and in facilitating visits to overseas medical schools, meetings and congresses, and in being a center through which the temporary occupation of professional chairs or exchange of professorships might be arranged. 4. The promotion of personal friendly intercourse between the members of the profession in this country and their brethren from overseas. To promote these objects a center has already been granted by the Royal Society of Medicine, where arrangements will be made to collect, file and circulate information on all matters of medical interest. Rooms will be available for conferences, discussions, demonstrations or exhibitions. In fact, the fellowship of medicine will act as a sort of central Cook's tourist office for travelers in the medical world. The primary object of this association is not to arrange postgraduate study: this is the care of a separate association, also under the egis of Sir William Osler, with which there will be the most friendly cooperation. Postgraduates are particularly desirous of continuous and intensive training in one or more circumscribed departments of medicine. But the fellowship caters for all visitors, not only those seeking postgraduate classes, but also those wishing to study our medical history, institutions and organizations, hospitals, infirmaries, dispensaries, asylums, fever hospitals, lying-in institutions, nursing homes and sanatoriums, or our state and municipal hygienic arrangements. It is proposed to help them to hear and join in the scientific medical life of this country and provide them with entertainments of medical interest. It will help them to see any one particular man operate or hear any special clinical demonstration; to work in any laboratory or study or in any library, or to visit any asylum or investigate any system of drainage.

Liquid Eggs from China

The report by Dr. A. W. J. MacFadden on the work of inspectors of food during 1917-1918, which has been issued by the Local Government Board, deals with the importation from China of eggs in liquid form. Before the war the bulk of this material went to Germany, and the small quantities brought here were used for industrial purposes and, to a limited extent, for confectionery. After the outbreak of war, large consignments arrived in this country as cargoes in prize ships, and since then large quantities have been imported in the ordinary course of trade. These products, Dr. MacFadden states, occasionally arrive in the form of whole egg mixed, but usually the egg yolk and egg albumin are sent separately. In the latter case the albumin may be sent in a fluid state with preservative added or in a crystalline dried form. Samples of yolk were found to contain boric acid in amounts varying from 1.35 to 2.08 per cent. Sometimes common salt up to 10 per cent. is used, with a smaller amount of boric acid. Until comparatively recently the use of this liquid egg for food purposes was confined to the manufacture of cakes, biscuits, etc. The amount of boric acid in the finished food as eaten is reduced to about 5 grains a pound. During the latter part of 1917, however, liquid egg began to appear on the market in large quantities packed for domestic use in small tins and jars. In this form the product was available for use in milk puddings, pancakes, etc., and when used for such purposes, the amount of boric acid consumed by the individual would be considerable. There is also good reason to believe that large quantities have for some time been used in restaurants for similar purposes. The employment of these boricized products for domestic and restaurant use is open to serious objection. In the case of the smaller receptacles sold at retail, some of the packers make a statement to the effect that the contents should not be used for omelets or scrambled eggs; but even this small measure of protection is not available to persons eating at hotels, restaurants and similar places. Dr. MacFadden suggests that, as the importation of egg products from abroad will necessarily increase in the future, it would be advantageous, from the points of view both of the health of the consumer and of economy in shipping space, if arrangements could be made for the product to be shipped as dried egg instead of in a liquid form. Dried egg imports have proved very successful, and if the eggs are prepared and packed properly in this form, they are a wholesome and useful foodstuff.

A National Register of Population

At a meeting of the National Birth-Rate Reconstruction Commission, promoted by the National Council of Public Morals, the need of a national register of population was put forward by Dr. T. H. C. Stevenson for Sir Bernard Mallet, the registrar-general. Dr. Stevenson said that there were in this country a large number of partial registers of the population, but the census remained the only complete register, and that, being revised only once in ten years, was of use only for statistical purposes. The partial registers included at present the national register, the food register, electoral registers, school attendance registers, sickness and unemployment insurance registers, and many others. All these were, generally speaking, independently compiled and maintained, the information obtained by one not being made available for the purposes of the others. The proposal favored by the registrar-general was that a single master register should be set up which would include every man, woman and child in the country. It would contain certain particulars of general interest about each, such as address, name, sex, date and place of birth, and occupation, with information as to marriage and children. But no single register could possibly contain all the information that might be wanted for its own special purposes by any one of the multifarious records referred to. The proposal was therefore to link each of these up with the general register as part of a single coordinated system, providing for the communication to each of the special registers of the information of common interest collected by the general register, and leaving each of them to amplify this according to their own requirements. With this object the general register might record, in code form, on which of the special registers the person was borne; and information of removals, etc., would be communicated to these as received. The general register alone should have complete canvassing organization, none of the others requiring to start de novo, but merely to fill in gaps in their knowledge concerning certain individuals. As the register would deal with many millions of names, it would have to be maintained in local sections through the country; but it would be necessary to maintain a single central index to all the local registers. Births, deaths and removals would all be reported to this index. The central organization should coordinate and control the local general registers. Under the scheme indicated, eugenists would in time be provided with pedigree records of the population comparable in accuracy with those already provided for prize live stock; and the field for research could be indefinitely extended by tracing the records of the progeny of various unions.

Proposed Drastic Reform in the Lunacy Laws

The present lunacy laws were passed with little regard for the treatment of incipient insanity. Under existing conditions, many patients, owing to the objection of their relatives to their being certified as insane, are kept in their homes so long that when ultimately they are sent to an asylum their cure, which might have been effected by early treatment, is hopeless. The committee appointed by the Conference of Visiting Committees of the Asylums has prepared a report stating that the present lunacy acts are effete and that drastic amendment is of urgent national importance. They recommend that the words "pauper," "lunacy," "lunatic" and "asylum" should be deleted from the lunacy laws; that the establishment by local authorities of special mental hospitals for the treatment of either incipient or actual mental disease should be encouraged; that such hospitals should comprise inpatient and outpatient departments; that no patient of such a hospital should be under certification until the medical director of the hospital considers it necessary that the patient should be transferred to an institution such as is now known as an asylum; that special mental hospitals should not be subject to the supervision of the board of control (the body appointed by the government to control the treatment of lunatics), and that no report should be made to that board concerning any patient under treatment therein; that in connection with every medical school a special mental hospital (psychiatric clinic) should be established, in which proper facilities should be provided for research, teaching and training; that every medical officer appointed to any institution for the care and treatment of the mentally afflicted should be required, within two years from his appointment, to hold a recognized diploma showing that he is specially skilled in the science of the cure of mental ailments; that voluntary boarders should be admitted to the institutions now known as public asylums, and that the lunacy acts and the mental deficiency act should be consolidated, and, with the rules and regulations made under those acts, thoroughly revised.

Scientific Meeting of the British Medical Association

During the four years of the war, the scientific meetings of the British Medical Association were suspended and only the political meetings of the representatives were held. The last ordinary annual general meeting was held in July, 1914, and it had been arranged to hold the following meeting at Cambridge, under the presidency of Sir Clifford Allbutt. This meeting was abandoned, because of the strain on the profession owing to the war. It has been found impossible for Cambridge to arrange to receive the association this year, but it hopes to do so in 1920. It was therefore suggested that a special meeting might be arranged this year for the discussion of clinical and scientific subjects, but on a smaller scale than usual. At a meeting, the proposal was laid before Lieut.-Gen. Sir John Goodwin, the director general of the army medical service, and representatives of the medical services of the British navy and air force and of the medical services of the Dominions and of the United States. In opening the proceedings, Sir Clifford Allbutt said that the time had come to relay old tracks and make plans for reconstruction, but that it had not been considered advisable to hold a full-dress meeting this year. A short scientific meeting could be held this year in London without any attempt at large organization or elaborate entertaining. Dr. J. A. MacDonald, chairman of the council, said that the main object would be to bring together workers from at home, the Dominions and the United States to garner knowledge and ideas from those who had studied war medicine and surgery. Lieut.-Gen. Sir John Goodwin thought that such a congress was most desirable. Much scientific work of the highest value had been done during the war, and the results were now being analyzed. It would be an immense advantage that they should be examined. All possible facilities would be given to assemble research workers from the forces overseas. Col. A. M. Whaley, United States liaison medical officer with the War Office, welcomed the idea on behalf of the American medical officers serving in Europe. Approval was also expressed by representatives of the Canadian, Australian and New Zealand medical service. All agreed that the meeting would be valuable in crystallizing the knowledge gained during the war. In view of the approaching departure of many medical officers, it was felt that the meeting should be held as soon as possible. It was provisionally agreed that the meeting should be held early in April and should last two or three days.

Industrial Fatigue

A research board has been appointed by the Department of Scientific and Industrial Research and the Medical Research Committee jointly to consider and investigate the relations of hours of labor and of other conditions of employment, including methods of work, to the production of fatigue, having regard both to industrial efficiency and to the preservation of health among the workers. The duty of the board will be to initiate, organize, and promote by research, grants or otherwise, investigations in different industries with a view to finding the most favorable hours of labor, spells of work, rest pauses and other conditions applicable to the various processes according to the nature of the work and its demands on the worker. For these investigations the board looks forward to receiving the help of employers and workmen in the industries which are studied, and in appropriate cases representatives of both will be invited to serve as temporary members of the board. The board includes Dr. C. S. Sherrington, F.R.S., professor of physiology, University of Oxford; Sir Walter Fletcher, F.R.S., secretary, Medical Research Committee; Dr. T. M. Legge, medical inspector of factories; Col. C. S. Myers, F.R.S., director of the Psychological Laboratory, Cambridge, and some directors of large firms.

Standard Illumination and Vision Testing

The Council of British Ophthalmologists appointed a committee consisting of eminent ophthalmologists and physicists to determine standards of illumination for Snellen's test types for distant vision. The committee has now issued an important report. The effect on visual acuity of variations in the illumination of test objects has been the subject of a series of careful investigations for many years. Two chief facts emerge: 1. There is a rapid rise in acuity as the illumination is increased from zero up to about two "foot candles" (one foot candle is the illumination received from a source of one candle power falling perpendicularly on a surface at a distance of one foot from the source). 2. Above three foot candles there is scarcely any appreciable rise in acuity. The results obtained by different observers are not entirely concordant, the discrepancies being attributable to variations in the test object: contrast, size of pupil, etc. For clinical purposes it appears to be sufficiently accurate to regard the results obtained with an illumination of three foot candles or more as valid and comparable under the ordinary conditions of clinical testing. But this minimum is by no means always insured in testing for military or other public services. Apart from the fact that the test types often do not conform to Snellen's criteria, they are frequently dirty, thus diminishing contrast, are varnished, thus giving rise to disturbing direct reflection of light, and are viewed under great variations of daylight, in rooms often ill suited for the purpose. It is possible to lay down precise and simple rules for the efficient illumination of test types. Two ordinary 20 watt tungsten lamps with straight filaments are fixed vertically 15 inches in front of the plane of the test card, one on each side at a horizontal distance of 12 inches from the vertical plane normal to and bisecting the card. One lamp is placed higher than the other, one being opposite the junction of the upper and middle thirds of the card, the other opposite the junction of the middle and lower thirds. Opaque, nonreflecting screens are fitted, so as to prevent direct light from the lamps reaching the candidate's eye. With new lamps the illumination on the test types will be of the order of ten foot candles. The ordinary variations of current, deterioration of lamps, and the darkening of the test card with age will not reduce the brightness of the test card so illuminated to a value less than that of a perfectly white surface receiving an illumination of three foot candles.

Marriages

Edward W. Northcutt, Lieut., M. C., U. S. Army, Torrington, Ky., on duty with the American Expeditionary Forces in France, to Miss Mariet Struts of Marinette, Wis., at the Base Hospital, Venes, France, Dec. 20, 1918.

Harry B. Burne, Lieut., M. C., U. S. N. R. F., on duty at the Naval Training Station, Great Lakes, Ill., to Miss Ethel Smith, of Iowa City, Ia., at Waukegan, Ill., February 7.

Walter Armstrong Noble, Lieut., M. C., U. S. Army, St. Mary's, O., to Miss Mildred L. Conner, of Berlin Heights, O., February 4.

Norman Edward Ditman, New York City, to Miss Grace E. Cumnock of Lowell, Mass., February 22.

Otto Emil Prellwitz, to Miss Wilhelmina Louise Klappert, both of New York City, Dec. 21, 1918.

Deaths

David Alexander Hodghead ⊕ San Francisco; Bellevue Hospital Medical College, 1884; aged 61; dean and professor of obstetrics and diseases of children in the College of Physicians and Surgeons, San Francisco; formerly president and secretary of the San Francisco Clinical Society, and secretary of the Medical Society of the State of California; editor of the Pacific Medical Journal from 1889 to 1892 and from 1898 to 1904; formerly superintendent of the City and County Hospital of San Francisco; died in San Francisco, February 5, from pneumonia following influenza.

John Ravenswood Hicks ⊕ **Major, M. C., U. S. Army,** Staten Island, N. Y.; University of Maryland, Baltimore, 1893; aged 46; ophthalmic surgeon to St. Vincent's Hospital of the Bureau of Richmond, New Brighton; acting assistant surgeon U. S. Army from 1902 to 1906, with service in the Philippine Islands; on duty with the 302d Tank Corps, American Expeditionary Forces; died in France, January 3.

William Stanton Gleason ⊕ Newburgh, N. Y.; New York University, New York City, 1886; aged 58; a specialist on internal medicine; president of the Medical Society of the State of New York in 1915; a Fellow of the New York Academy of Medicine; senior attending physician to St. Luke's Hospital, and consulting physician to the Highland Hospital; died at his home, February 3, from nephritis.

George Pierce, Upper Montclair, N. J.; Johns Hopkins Medical School, Baltimore, 1907; aged 35; at one time a member of the Medical Society of New Jersey and instructor in urology in Johns Hopkins Hospital, Baltimore; a research chemist for the Colgate manufacturing plant, Jersey City, N. J.; died at his home, February 4, from injuries received in an explosion of chemicals, the day before.

Charles Hubart Lovewell, Chicago; University of Michigan, Ann Arbor, 1871; aged 70; a member of the Illinois State Medical Society; a pioneer practitioner of Englewood, where he located in 1875; for many years local surgeon of the Lake Shore and Rock Island System; a member of the town of Lake school board from 1888 to 1890; died at his home, February 9, from cerebral hemorrhage.

James H. Wilson ⊕ Dover, Del.; University of Pennsylvania, Philadelphia, 1867; aged 76; secretary of the Medical Society of Delaware, Examining Board; president of the State Medical Society for several years; local surgeon for the Pennsylvania System since 1874; a member of the board of trustees of the Delaware State Hospital, Farnhurst; died at his home, February 1.

William Shorter Bull ⊕ **Lieut., M. C., U. S. Army,** Irvington, N. J.; New York Homeopathic Medical College, New York City, 1914; aged 32; on duty with the 114th Infantry, Twenty-Ninth Division, American Expeditionary Force; while crossing the River Meuse, France, on a temporary bridge under fire, Oct. 11, 1918, was instantly killed by the explosion of a shell.

Samuel S. Washburn, Lafayette, Ind.; University of Louisville, Ky., 1861; aged 79; a member of the Indiana State Medical Association; a veteran of the Civil War, in which he served as assistant surgeon of the Sixteenth Indiana Volunteer Infantry; for eighteen years a member of the Indiana Council; a member of the City Board of Health; died at his home, February 4.

Alba Gustavus Walker ⊕ **Capt., M. C., U. S. Army,** Houlton, Me.; College of Physicians and Surgeons, Boston, 1902; aged 43; who was honorably discharged from the service, Nov. 30, 1918; is reported to have died, February 4, in Edmundston, N. B., from the effects of poison, self-administered, it is believed, with suicidal intent.

Martin Maximilian Holzman ⊕ **Lieut., M. C., U. S. Army,** New York City; College of Physicians and Surgeons in the City of New York, 1915; aged 27; assistant attending genito-urinary surgeon at the West Side Hospital, New York City; on duty at Fort Oglethorpe, Ga.; died, Oct. 28, 1918, from acute bronchopneumonia.

Frederick Arthur Henderson ⊕ **Lieut., M. C., U. S. Army,** Kokomo, Ind.; Jefferson Medical College, 1912; aged 32; who entered the Army in August, 1917, and was on duty at Fort Benjamin Harrison, Ind., and later at Camp Zachary Taylor; died in Fort Bayard, N. M., Nov. 30, 1918, from pulmonary tuberculosis.

John Groat Corson ⊕ **Lieut., M. C., U. S. Army,** Binghamton, N. Y.; University of Syracuse, N. Y., 1915; aged 27; who had been on duty with a medical detachment of the British E. F. in France, and was thence invalided to England; died in a hospital in London, Oct. 23, 1918, from lobar pneumonia.

William Charles Griggs ⊕ Philadelphia; New York University, New York City, 1890; aged 51; for several years a missionary of the American Baptist Missionary Union in Burmah; a resident of Philadelphia for thirteen years; died suddenly in the Misericordia Hospital, Philadelphia, February 3.

Benjamin Franklin Currie, Burke, Texas; University of Texas, Galveston, 1911; aged 30; a member of the State Medical Association of Texas; formerly acting assistant surgeon U. S. P. H. S., with station at Fort Stanton, N. M.; died at San Angelo, Texas, January 3, from pulmonary tuberculosis.

Noah Norman McFarland ⊕ **Lieut., M. C., U. S. Army,** Memphis, Tenn.; University of Tennessee, Nashville, 1913; aged 28; died in Camp Greene, Charlotte, N. C., Dec. 16, 1918, from the effects of incised and lacerated wounds of either side of the neck, severing both jugular veins.

Oscar Gilbert Smith, New York City; College of Physicians and Surgeons in the City of New York, 1854; aged 88; a fellow member of the New York Academy of Medicine since 1866; a charter member of the Medical Society of the Greater New York; died at his home, February 4.

Ingvald Martinius Josephson Hotvedt ⊕ Muskegon, Mich.; University of Minnesota, Minneapolis, 1899; aged 46; a specialist in surgery; a linguist of note, and for several years a missionary in China; was shot and killed in his office, February 10, by an angered or insane patient.

Erlo Elsten Kennedy, Denver; Baltimore Medical College, 1905; aged 38; secretary of the Colorado State Board of Health; for two years a member of the House of Representatives, and chief clerk of that body; died at his home, February 4, from influenza.

Knight William Field ⊕ **Lieut., M. C., U. S. Army,** Dallas, Texas; Tulane University, New Orleans, 1900; aged 42; formerly on duty at Camp Hancock, Augusta, Ga., and later with the American Expeditionary Forces in France; died in France, Oct. 11, 1918.

Thomas J. Horsley ⊕ Mangum, Okla.; Barnes Medical College, St. Louis, 1891; aged 46; a specialist in diseases of the eye, ear, nose and throat; secretary of the Greer County, Okla., Medical Society; was found dead in his office, January 9, from heart disease.

Burton Paul Bradley ⊕ **Lieut., M. C., U. S. Army,** Rome, Ga.; Emory University, Atlanta, Ga., 1915; aged 25; assigned to duty with field hospital, No. 347, Sanitary Train 312, Camp Pike, Little Rock, Ark.; died Oct. 16, 1918, from acute bronchial pneumonia.

Daniel MacDonald, New York City; New York Homeopathic Medical College, New York City, 1912; aged 58; professor of pathology in Fordham University, who formerly occupied a similar position in the Woman's College; died at his home, February 5, from Bright's disease.

Harmar D. Moore, New Lexington, Pa.; Jefferson Medical College, 1873; at one time a member of the Medical Society of the State of Pennsylvania; for fifty years a practitioner of Somerset County and Pittsburgh; died at his home, February 7.

George C. Watson, New Concord, Ohio; Starling Medical College, Columbus, Ohio, 1889; aged 52; postmaster of New Concord for twelve years and cashier of the First National Bank; died at his home, January 28, from carcinoma.

Benjamin George Jones ⊕ **Lieut., M. C., U. S. Army,** Oklahoma City, Okla.; University of Oklahoma, Norman, and Oklahoma City, 1917; aged 26; on duty at Newport News, Va.; died Oct. 17, 1918, from double lobar pneumonia.

Lumus C. Newton, Detroit, Mich.; College of Physicians and Surgeons, Baltimore, 1880; aged 64; formerly a member and president of the Detroit School Board; died in Grace Hospital, Detroit, January 31, from acute nephritis.

Leon Hirsch ⊕ Pittsburgh, Jefferson Medical College, 1896; aged 42; also a graduate of the Pittsburgh College of Pharmacy; a member of the staff of Passavant Hospital, Pittsburgh; died recently in Mercy Hospital, Pittsburgh.

Valentin T. Guanio y Tinio, Gapan, P. I.; University of the Philippines, Manila, 1915; is reported to have died recently from bronchopneumonia.

⊕ Indicates "Fellow" of the American Medical Association.

Jonas M. O. Tufty ⊕ Duluth, Minn.; University of Christiania, Norway, 1885; aged 61; for thirty years a practitioner of Duluth, and for two terms a member of the library board; died at his home, January 4, from heart disease.

Harry Robinson Parker ⊕ **Lieut., M. C., U. S. Army,** Williamson, W. Va.; University of Vermont, Burlington, 1907; aged 34; on duty at Hazelhurst Field, Mineola, L. I.; died Dec. 23, 1918, from lobar pneumonia.

Stephen James Hawes ⊕ **Lieut., M. C., U. S. Army,** Dover, N. C.; University College of Medicine, Richmond, Va., 1911; aged 32; on duty at Camp Jackson, Columbia, S. C.; died Dec. 14, 1918, from bronchial pneumonia.

Bryant Carr Rudder ⊕ **Lieut., M. C., U. S. Army,** Walker Springs, Ala.; Universities of Nashville and Tennessee, Nashville, 1911; aged 32; on duty at Fort Oglethorpe, Ga.; died Oct. 14, 1918, from bronchopneumonia.

Samuel G. Crawford, Sedalia, Mo.; Kentucky School of Medicine, Louisville, 1880; aged 77; colonel of the Forty-Ninth Kentucky Volunteer Infantry, during the Civil War; died at his home, January 31.

Robert T. Connally, Mena, Ark. (license, Arkansas, 1903); aged 74; at one time a member of the Arkansas Medical Society; a Confederate veteran; died at the home of his son, in Rocky, Ark., January 30.

Hugh Zollicoffer Browne ⊕ **Lieut., M. C., U. S. Army,** Kosciusko, Miss.; Tulane University, New Orleans, 1911; aged 32; on duty at Fort Oglethorpe, Ga.; died Oct. 22, 1918, from acute bronchial pneumonia.

Glenn Elbert Haughey ⊕ **Lieut., M. C., U. S. Army,** Wakeeney, Kan.; Kansas Medical College, Topeka, 1908; aged 34; on duty at Fort Oglethorpe, Ga.; died Oct. 24, 1918, from acute bronchopneumonia.

Matthew Joseph Foley ⊕ **Lieut., M. C., U. S. Army,** New Haven, Conn.; Eclectic Medical Institute, Cincinnati, 1917; aged 27; died in Camp Meade, Admiral, Md., Oct. 10, 1918, from bronchopneumonia.

John Hamlin Traylor ⊕ **Capt., M. C., U. S. Army,** Cuero, Tex.; Vanderbilt University, Nashville, Tenn., 1909; aged 31; on duty at Camp McArthur, Tex.; died Oct. 26, 1918, from acute meningitis.

James Harvey Todd, Major, C. A. M. C., Toronto, Ont.; University of Toronto, Ont., 1905; aged 35; on duty at Quebec; died in that city, Oct. 17, 1918, from pneumonia following influenza.

John Richard Fischer ⊕ **Lieut., M. C., U. S. Army,** Utica, N. Y.; University and Bellevue Hospital Medical College, 1917; aged 26; died Oct. 31, 1918, from chronic pulmonary tuberculosis.

James S. Kugler, Sharon, Pa.; Eclectic Medical College of Pennsylvania Philadelphia, 1869; aged 89; said to have been the oldest practitioner of Mercer County; died at his home, January 28.

Charles Francis Cropp ⊕ **Lieut., M. C., U. S. Army,** Independence, Ore.; Willamette University, Salem, Ore., 1913; age 33; died January 6, from bronchopneumonia following influenza.

Orin Worrett Robe ⊕ **Capt., M. C., U. S. Army,** Portsmouth, O.; Starling Medical College, Columbus, O., 1891; aged 50; a specialist in surgery; died Oct. 25, 1918, from chronic myocarditis.

Murat Halstead Scott ⊕ **Lieut., M. C., U. S. Army,** Harrison, O.; University of Cincinnati, 1914; aged 28; on duty at Fort Oglethorpe, Ga.; died Oct. 19, from lobar pneumonia.

David D. Talbott, Lewistown, Ill.; College of Physicians and Surgeons, Keokuk, Iowa, 1864; aged 81; was found dead in his office, January 18.

Orange C. Darling, Riverside, Calif.; Eclectic Medical Institute, Cincinnati, 1882; aged 62; died in the Loma Linda Sanitarium, January 21.

Alonzo Caldwell Miller, Washington, D, C.; Howard University, Washington, D. C., 1894; aged 47; died at his home, January 20.

John H. Kern ⊕ St. Louis; Missouri Medical College, St. Louis, 1894; aged 55; died at his home, January 16, from aneurysm.

Luther T. Cheatham, Louisville (Ky.) Hospital College of Medicine, Louisville, 1891; aged 49; died at his home, January 16, from pulmonary abscess.

Walter W. Holloway, Lexington, Ky.; University of Louisville, Ky., 1880; aged 61; died at his home, January 18, from chronic nephritis.

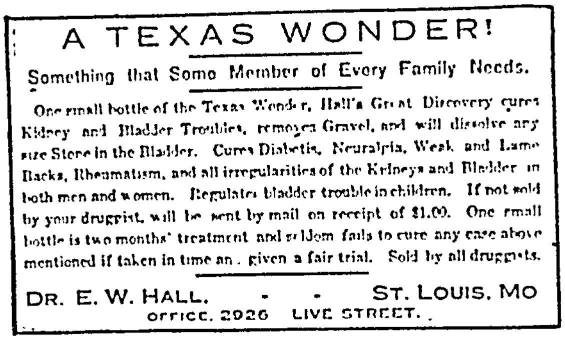
The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

MISBRANDED NOSTRUMS

How the Bureau of Chemistry Is Protecting the Public Against "Patent Medicines" Sold Under Fraudulent or Misleading Claims

Hall's "Texas Wonder."—Shipped about April, 1917, by E. W. Hall, St. Louis. Falsely and fraudulently claimed to be a great discovery for kidney and bladder troubles and diabetes, and to dissolve gravel. Condemned, forfeited, and ordered destroyed by the court.—[*Notice of Judgment No. 5957.*]



A TEXAS WONDER!

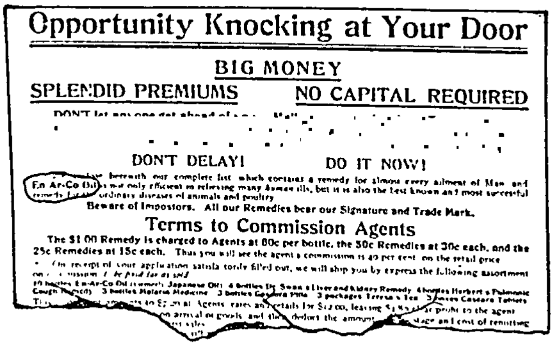
Something that Some Member of Every Family Needs.

One small bottle of the Texas Wonder, Hall's Great Discovery cures Kidney and Bladder Troubles, removes Gravel, and will dissolve any size Stone in the Bladder. Cures Diabetis, Neuralgia, Weak and Lame Backs, Rheumatism, and all irregularities of the Kidneys and Bladder in both men and women. Regulates bladder trouble in children. If not sold by your druggist, will be sent by mail on receipt of $1.00. One small bottle is two months' treatment and seldom fails to cure any case above mentioned if taken in time and given a fair trial. Sold by all druggists.

DR. E. W. HALL. - - ST. LOUIS, MO
OFFICE, 2926 LIVE STREET.

King's Liver and Kidney Alterative and Blood Cleanser.—Shipped in January, 1916, by Chas. A. Ritchey, Chicago. Analysis showed the product to consist essentially of a solution of Epsom salt, aloes, quassia, caramel and oil of sassafras. Falsely and misleadingly represented as to composition, and fraudulently represented as a remedy for erysipelas, syphilis, female weakness, "cancerous humors," etc. Fine, $200 and costs.—[*Notice of Judgment No. 5985.*]

En-Ar-Co Oil.—Shipped in January, 1917, by the National Remedy Co., New York City, under the name of Chas. E. Crittenden Co. Analysis showed the preparation to be essentially a water-alcohol solution of amyl and ethyl alcohols, acetone, capsicum extractives, a saffrol-containing oil, a light mineral oil, and a fixed vegetable oil. Falsely and fraudulently represented as a remedy for asthma, rheumatism, snake bites, corns and bunions, chicken cholera, hog cholera, lockjaw, spavin and heaves. Fine, $50.—[*Notice of Judgment No. 6002.*] This preparation was investigated by the Propaganda Department and analyzed by the A. M. A. chemical laboratory in 1911, and exposed in The Journal, July 29, 1911.



Opportunity Knocking at Your Door

BIG MONEY

SPLENDID PREMIUMS NO CAPITAL REQUIRED

DON'T let any one get ahead of [illegible]

DON'T DELAY! DO IT NOW!

[illegible] herewith our complete list which contains a remedy for almost every ailment of Man and [illegible] En-Ar-Co Oil is not only efficient in relieving many human ills, but it is also the best known and most successful remedy for the ordinary diseases of animals and poultry

Beware of Impostors. All our Remedies bear our Signature and Trade Mark.

Terms to Commission Agents

The $1.00 Remedy is charged to Agents at 60c per bottle, the 50c Remedies at 30c each, and the 25c Remedies at 15c each. Thus you will see the agent's commission is 40 per cent on the retail price.

On receipt of your application satisfactorily filled out, we will ship you by express the following assortment on commission, to be paid for as sold:

10 bottles En-Ar-Co Oil (formerly Japanese Oil), 4 bottles Dr. Swan's Liver and Kidney Remedy, 4 bottles Herbert's Pulmonic Cough Remedy, 3 bottles Malaria Medicine, 3 bottles Cascara Pills, 3 packages Teresa's Tea, 3 boxes Cascara Tablets

This assortment amounts to $7.20 at Agents' rates and retails for $12.00, leaving $4.80 clear profit to the agent [illegible] on arrival of goods and then deduct the amount [illegible] postage and cost of remitting [illegible]

Lindsey's Improved Blood Searcher.—Shipped in February, 1916, by the W. J. Gilmore Drug Co., Pittsburgh. Analysis showed the preparation to be an alcohol-water solution of sugars, salicyclic acid, aromatic oils, plant extractives, and calcium salts, with indications of guaiac. Falsely and fraudulently represented as a blood purifier and a remedy for diseases of women, malaria, cancer, sore eyes, piles, etc. Fine, $50.—[*Notice of Judgment No. 5973.*]

White Eagle's Indian Oil Liniment.—Shipped in January, 1917, by Aaron P. and Caroline McCarty, doing business as the White Eagle Medicine Co., Piqua, Ohio. Analysis showed the product to consist essentially of kerosene and a saponifiable oil, together with a small amount of oil of sassafras. Falsely and fraudulently represented to be a cure for diphtheria, hay-fever, goiter, deafness, rheumatism, etc. Fine, $50 and costs.—[*Notice of Judgment No. 6090.*]

Aqua Nova Vita.—Shipped in December, 1914, by the Aqua Nova Vita Co., Easton, Pa. Falsely and fraudulently claimed to be an effective remedy in cancer, syphilis, hay-fever, hardening of the arteries, tuberculosis, locomotor ataxia, Bright's disease, diabetes, etc. Fine, $75.—[*Notice of Judgment No. 6136.*]

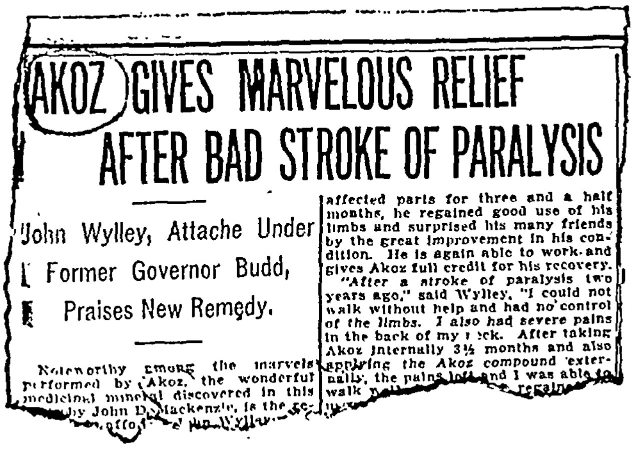
Brown's New Consumption Remedy.—Shipped in March, 1916, by David H. Brown, trading as the Magnolia Remedy Co., St. Augustine, Fla. Analysis showed the product to be a dark brown emulsion, containing essentially creosote, phosphoric acid, sodium phosphate, Epsom salt, glucose, sugar and a trace of an alkaloid. Falsely and fraudulently represented as a remedy for consumption, pneumonia, la grippe, etc. Fine, $50 and costs.—[*Notice of Judgment No. 6143.*]

Akoz.—Consigned in August, 1917, by the Natura Co., San Francisco, to a concern in Bilbao, Spain. There were various products in the consignment, one being "Akoz Ointment," represented as "A Natural Remedy for Skin Diseases . . . Hemorrhoids," etc.; another was "Akoz Rectal Suppositories," for hemorrhoids, ulcerations, etc.; still another was "Akoz Powder"[1] for "kidney troubles," rheumatism, dyspepsia, etc.; "Akoz Dusting Powder," for eczema, chronic ulcers, acne, etc.; "Akoz Plaster," for rheumatism, neuritis, pain in back, etc.; "Akoz Compound," for rheumatism, neuralgia, etc. The claims for all of these products were declared to be false and fraudulent, as they contained no ingredients or combination of ingredients capable of producing the therapeutic effects claimed. The court entered judgment of condemnation and forfeiture, and ordered that the stuff should be destroyed.—[*Notice of Judgment No. 6026.*]



AKOZ GIVES MARVELOUS RELIEF AFTER BAD STROKE OF PARALYSIS

John Wylley, Attache Under Former Governor Budd, Praises New Remedy.

Noteworthy among the marvels performed by Akoz, the wonderful medicinal mineral discovered in this [illegible] by John D. Mackenzie, is the re- [illegible]

affected parts for three and a half months, he regained good use of his limbs and surprised his many friends by the great improvement in his condition. He is again able to work and gives Akoz full credit for his recovery.

"After a stroke of paralysis two years ago," said Wylley, "I could not walk without help and had no control of the limbs. I also had severe pains in the back of my neck. After taking Akoz internally 3½ months and also applying the Akoz compound externally, the pains left and I was able to walk [illegible] regained

Fenner's Kidney and Backache Remedy.—Shipped in January, 1913, by the M. M. Fenner Co. Analysis showed the stuff to contain over 11 per cent. alcohol, potassium acetate and methyl salicylate. Falsely and fraudulently represented as a cure for inflammation of the kidneys, catarrh of the bladder, heart disease, leukorrhea, etc. Fine, $25.—[*Notice of Judgment No. 6119.*]

Wine of Chenstohow.—Shipped in March, 1915, by A. Skarzynski & Co., Buffalo. Analysis showed the stuff to contain over 17 per cent. alcohol, nearly 10 per cent. reducing sugars, and small amounts of emodin. Falsely and fraudulently claimed to be a remedy for stomach affections, and a cure for general debility, loss of strength, piles, etc. Fine, $75.—[*Notice of Judgment No. 6125.*]

Correspondence

REPORT OF A CASE OF CYANOSIS AT CAMP JACKSON, S. C., DUE TO POISONING FROM SHOE DYE

To the Editor:—Recently (The Journal, Feb. 8, 1919, p. 395) I reported a series of seventeen cases of cyanosis due to methemoglobinemia caused by poisoning by a shoe dye. All these cases occurred at Camp Johnston, Fla. Seven of the seventeen men gave a history of having had their shoes or their puttees dyed the day they became cyanotic, or of having worn newly dyed shoes and puttees on that day. One other man who had been cyanotic several weeks before he was interviewed asserted that his shoes were dyed after he left the hospital. Six of the other nine men who had gone overseas and whose history could not be obtained at the last writing have been heard from and have given a positive history. The evidence against the shoe dye was convincing, both from the experimental poisoning of white mice and of several men volunteers, and from the chemical examination of the dye, which showed the presence of nitrobenzene or some compound containing the grouping

. Most of the cases of poisoning at Camp Johnston were in recently commissioned student officers who were discarding their canvas puttees for leather puttees worn by officers. In order to make the light colored tan shoes furnished by the Qua[illegible] master's Department match the dark colored leath[illegible] worn by officers, the shoes and sometimes bo[illegible] puttees were dyed by a special brown oil[illegible] all but one of the Camp Johnston cases th[illegible] at a certain boot-black stand in Jacksonvil[illegible] however, the dye was bought of a well kno[illegible] Jacksonville, which has branch stores in all t[illegible] a fact which made me curious to know whether [illegible] of methemoglobinemia had not occurred at other [illegible]

Through the kindness of Major W. W. Her[illegible] chief of the medical service at Camp Jackson, S. C. [illegible] me of an unexplained case of cyanosis at the base [illegible] at Camp Jackson, and who investigated the case at my [illegible] with reference to possible poisoning from a shoe dye [illegible] able to furnish the history:

> Lieut. H. R. H. D. C., admitted to the officers' ward of the hospital of Camp Jackson, S. C., July 25, 1918, had been told [illegible] friend that his face and lips were blue. A little later he had nausea and headache, but did not feel bad enough to go to bed. Later his friends insisted that he consult a physician on account of his strange color. At 9:30 p. m. on admission to the hospital there were headache, nausea, vomiting and extreme cyanosis. The pulse was frequent, weak, and of low pressure. The heart sounds were feeble. The skin was very cyanotic, cold and sweating. The patient was exhausted, vomited, and complained of headache. The heart rate was 100 and regular. There

of th[illegible] pounds advised by Laboratory, 1916.

[1] An examination in the A. M. A. Chemical Laboratory showed [illegible]owder contained 2.2 per cent. of lead sulphate. In view [illegible] results which have followed the internal use of com[illegible] small amounts of lead, the Natura Company was [illegible] o[illegible]ratory of the finding (Rep. A. M. A. Chemical [illegible]3).

tuberculosis.

⊕ Indicates "Fellow"

was a slight systolic murmur over the precordia, not transmitted. There were a few sibilant and subcrepitant râles at the right upper anterior chest, with relative dulness at the angle of the right scapula. The rest of the physical examination was negative. On the following morning the patient felt very much better. The cyanosis disappeared in about twelve hours. No chemical tests were made. The diagnosis was "heat exhaustion and acute indigestion."

Jan. 8, 1919, Major Herrick received the following letter from the patient, who had been honorably discharged and was practicing dentistry in West Virginia:

"I am pleased to say that I *did* use a dye on my shoes and puttees the evening before I was taken to the base hospital at Camp Jackson. I do not know the name of the dye I was using, but it was bought from the 317th F. A. Canteen."

It is evident from the report of these cases that the use of russet shoe dyes is dangerous; even those dyes that are "guaranteed odorless" can produce marked cyanosis. Shoes and puttees should not be worn for three or four days after they have been dyed, and they should never be dyed while worn. The orange colored cleaning liquids and the russet pastes for polishing are harmless and may be safely and freely used.

RICHARD E. STIFEL, M.D.,
Camp Johnston, Jacksonville, Fla.
Captain, M C., U. S. Army; Chief of Laboratory, Base Hospital.

"METHEMOGLOBINEMIA DUE TO POISONING BY SHOE DYE"

To the Editor:—The article in THE JOURNAL, February 8, p. 395, on "Methemoglobinemia Due to Poisoning by Shoe Dye" is interesting, but there are some facts which make it appear doubtful that Dr. Stifel is correct in his judgment as to the toxic agent. I have had occasion to examine considerable numbers of shoe dyes, and in all cases have found nitrobenzene present in large percentages. It is, in fact, extremely difficult to prepare a satisfactory commercial product of this type without the use of nitrobenzene in substantial quantity. For that reason it seems highly probable that if this were truly the cause of the symptoms described in Dr. Stifel's paper, there would have been a great number of similar cases reported. This material has been used in large quantities for many years and under conditions just as likely to produce poisoning as those described by Dr. Stifel. Is it not possible that the symptoms were due, not to nitrobenzene itself, but to some by-product accompanying it, such as the highly toxic tetranitromethane, which is frequently produced in the manufacture of trinitrotoluene?

CARL S. MINER, Chicago.

STATISTICAL STUDY OF THE INFLUENZA EPIDEMIC

To the Editor:—The American Public Health Association, Vital Statistics Section, appointed a Committee on Statistical Study of the Influenza Epidemic, Nov. 20, 1918. Under the auspices of this committee, a meeting of the state and municipal registrars in the Eastern states was held at the Hygiene Laboratory of the University of Pennsylvania, Philadelphia, November 29 and 30. At this initial conference there were present also several private statisticians interested in the public health statistics of the epidemic and the results to be derived from study of such data. A series of suggestions was made up, mimeographed and sent to statistical and public health workers for criticism. At the meeting of the Vital Statistics Section in Chicago, December 11, the committee submitted a report on its activities and asked for authority to continue further inquiry into a program of statistical study of the epidemic. The section authorized the continuance of the committee and provided that representatives of the United States Bureau of the Census, of the United States Army and Navy, of the United States Public Health Service, of the state and municipal health boards, and the various statistical, sociological, actuarial and economic associations be represented thereon. The committee was specifically authorized to act in an advisory capacity, first, to outline the various sources of data and the minimum standards of tabular and registration practice to be observed by several organizations providing data, and, second, to bring in recommendations on the pathometric or mathematical analysis of published epidemic data. The committee was divided into four subcommittees:

SUBCOMMITTEE A.—*Registration and Tabulation Practice of the Federal Departments:* William H. Davis, M.D., chief statistician, Division of Vital Statistics, Bureau of the Census, chairman; Richard C. Lappin, recorder.

SUBCOMMITTEE B.—*Registration and Tabulation Practice of the State Departments and Commissions:* Otto R. Eichel, M.D., director, Division of Vital Statistics, New York State Department of Health, Albany, chairman; Edwin W. Kopf, recorder.

SUBCOMMITTEE C.—*Registration and Tabulation Practice of Municipal Boards of Health and of Private Public Health Agencies:* Charles Scott Miller, M.D., Philadelphia Department of Health, chairman.

SUBCOMMITTEE D.—*Pathometry* (mathematical analysis and interpretation) *of the Epidemic:* Charles C. Grove, Ph.D., Columbia University, chairman; Arne Fisher, F. S. S., recorder.

Mr. E. W. Kopf was delegated to act as chairman of the general committee and to coordinate the work of the several subcommittees. The General Committee on Influenza Statistics of the Vital Statistics Section was authorized to cooperate in statistical matters with the Influenza Reference Committee of the entire association. (See "Influenza Bulletin: A Working Program," American Public Health Association, Boston, Dec. 13, 1918.)

At the Washington meeting of Subcommittee A, the subjects taken up were: estimates of population; the obtaining of estimates of army and navy populations by five year age periods, through random sampling if necessary, but by direct tabulation of army and navy enlistment records if possible; the causes of death reported during the epidemic, to be classified in accordance with the Manual of the International List of Causes of Death and the Index of Joint Causes as published by the Bureau of the Census; infant mortality, studied in such a manner as to show what part of this mortality was probably due to birth mortality arising out of influenzal illness of the mother and to the factor of neglect; norms of mortality during September, October and November.

It was also indicated that it was unwise to draw any conclusions from statistics of variations in bacterial flora at various stages in the epidemic or in different localities, unless it was shown that all laboratory conditions had been properly controlled. The army was requested to supply statistics as to influenzal sickness classified by five year age periods, by date of onset, by duration of illness in days, and by principal complications, showing fatality or lethal rates for 100 completed cases.

Subcommittee B considered the more intimate statistics of the epidemic in the states. The subcommittee pointed out that in certain cities and for certain states valuable data were available in the files which would lead to the determination of the norm of mortality during the fall and winter months of the year. The social statistics of the epidemic were emphasized. It was urged that statistics of the effect of the epidemic on the family should be collected. State and municipal governments were urged to make preparations necessary for the proper statistical study of the epidemic data.

The Subcommittee on Municipal Statistics discussed chiefly the available data in the files of maternity clinics and visiting nursing associations. It was indicated that thorough study of these records would bring out some of the important facts on the obstetric data of the epidemic.

The Subcommittee on Pathometry has outlined for itself the problems of mathematically testing and graduating the crude compiled data for norms of infant and adult mortality. The subcommittee has in mind the frequency curves of mortality from the several important causes of death during the fall and winter months of the year, especially the curves for infant mortality considered as (*a*) "birth mortality" and (*b*) "true infantile mortality." By means of modern analytic methods it was aimed to determine the true "excess mortality" during the epidemic. It was planned also to fit various curves to the observed epidemic data and to compute the equations and the constants of the distributions in the several areas under observation (mean, mode, dispersion, skewness, "excess").

The Subcommittee on Pathometry also anticipated that it could determine by delicate mathematical tests the *probable* date of the beginning, "peak" and ending of the several waves or phases of the epidemic in the various communities; and possibly, the approximate differential equations representing the several recurrences or recrudescences of the epidemic could be established.

The methods of higher analysis applied to the influenza epidemic data can be of service to preventive medicine in the study of other diseases. The profession of statistics is confronted with an opportunity for unparalleled service to the medical sciences, among them preventive medicine.

Edwin W. Kopf, New York,
General Chairman, Committee on Statistical Study of the Influenza Epidemic, Section on Vital Statistics, American Public Health Association.

EYELASH IN THE CANALICULUS

To the Editor:—I note in The Journal, January 25, p. 275, the report of "A Unique Eye Case," an eyelash being found lodged in the canaliculus. I have had at least two similar cases. In each, there was experienced sudden irritation of the eye, and inspection revealed a lash partly protruding from the canaliculus. This was readily drawn out, with complete and immediate relief.

Edwin A. Clarke, M.D., Akron, Colo.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

OINTMENT FOR SCABIES—REMOVAL OF WARTS BY RADIUM —TRAGACANTH CREAM

To the Editor:—1. Please give a good prescription for scabies. 2. Please describe the best way to remove warts from the hands without electricity. 3. What treatment would you advise for a woman whose skin is dry but who develops a rash on the face, and whose eyes swell when the ordinary face creams are used? D. W. A.

Answer.—1. A good prescription is precipitated sulphur, Peruvian balsam, and green soap, each from 20 to 30 grains; zinc oxid, 2 drams, and petrolatum to make an ounce. This is rather a weak ointment, but is not likely to produce irritation like a full sulphur ointment. Patients should have a bath and a good scrub with soap and water at bedtime, and the ointment should be rubbed into the affected parts thoroughly. This may be done every night or every other night, according to the amount of irritation that occurs, for three or four applications. The dermatitis that may occur from it can be treated by bland ointments, such as a zinc oxid ointment containing 2 drams zinc oxid to 1 ounce petrolatum.

2. Among many other methods, warts may perhaps best be treated by radium. The radium is applied by applicator to the wart a sufficient length of time to produce a dry dermatitis. How long this is depends on the amount of radium in the applicator.

3. The following tragacanth lotion might be utilized:

Tragacanth	80 grains
Glycerin	1 ounce
Boric acid	½ ounce
Oil of bergamot	20 drops

Water to make a pint.

Dissolve the tragacanth and glycerin in the water by warming gently. Cool and add the oil of bergamot.

PREVENTION OF HEADACHE FOLLOWING LUMBAR PUNCTURE

To the Editor:—Do you know of any method of preventing the intense headache that not infrequently follows lumbar puncture for diagnostic purposes? Treating a large number of cases of syphilis, and seeing quite a number for other men, I have frequent occasion to do lumbar punctures. In a considerable percentage of these cases, even when every precaution is taken and the patient *remains* in bed for twenty-four hours after the puncture, a very severe headache follows. This headache may last from two or three to five or six days. It is immediately relieved if the patient takes a recumbent position, but starts again on arising. It is sometimes accompanied by vomiting. I have found that atropin will usually stop the vomiting, but as yet have found nothing that has any effect on the headache except lying down.

A few years ago—noting that I never have this symptom following Swift Ellis treatments (of which I had then done several hundreds) I thought it could be avoided by replacing the fluid removed by autogenous serum. This did not prove true, however, the same number of persons getting the headache as after simple puncture.

I have never to my recollection had the reaction in a case in which the spinal fluid showed evidence of disease of the nervous system. It is always in the cases in which the fluid is found to be negative.

In the literature of the past few years I have seen only one reference to the condition, and there it was suggested that the patient be kept in bed for twenty-four hours.

Realizing the importance of fluid examination in all cases of syphilis, I am very much interested to know if any one has found a way of preventing this very distressing symptom, or of helping it after it has once developed.

H. Le Baron Peters, M.D., Bridgeport, Conn.

Answer.—The intense headache in question may practically always be prevented if two conditions are rigidly observed: first, to use a needle of small caliber, preferably not exceeding 0.8 or even 0.6 mm. in diameter; second, to keep the patient recumbent for forty hours. By experiment and experience on human beings, Sicard of Paris learned that the puncture in the dura mater does not close under thirty hours and generally requires from thirty-four to thirty-six hours. He believes that the headache is caused not by the trivial amount of fluid taken for examination but by constant seepage through the punctured dura. A neurologist who has followed this advice in handling a large number of cases for nearly five years states that, during that time, he has had only two cases of severe headache following lumbar puncture.

WILDROOT DANDRUFF AND ECZEMA CURE

To the Editor:—Will you please publish under "Queries and Minor Notes" the composition of "Wildroot Dandruff and Eczema Cure" marketed by the Wildroot Chemical Co. of Buffalo, N. Y.?

Wm. S. Robertson, M.D., Charleston, W. Va.

Answer.—The pamphlet, "Cosmetic Nostrums," issued by the Propaganda department of The Journal has the following to say about this product: "This preparation, put on the market by the Wildroot Chemical Company, Buffalo, N. Y., is thus characterized by Dr. Harvey W. Wiley in his book '1001 Tests,' revised edition: 'Contains arsenic, and some phenolic body, probably resorcin; perfumed and colored. The trace of alkaloidal material present was too small for identification. Contains 40 per cent. of alcohol, as declared, and less than one half of 1 per cent. of nonvolatile matter. Claims that it is an herb compound and a positive remedy for eczema and dandruff obviously untenable.'"

BENZYL ALCOHOL

To the Editor:—The following appeared in the Chicago *Tribune*, Feb. 17, 1919:

"Dr. David I. Macht of Johns Hopkins University has discovered a new local anesthetic that is about forty times less toxic than cocain.

"The drug itself—benzyl alcohol, or phenmethylol—is not new, but its properties in producing local anesthesia are in the nature of a complete discovery that is attracting much attention in medical and surgical circles."

What are the facts in the case? Reader, Chicago.

Answer.—The paragraph quoted is correct. While experience alone will tell whether or not the local anesthetic comes up to the expectations of its discoverer, it was deemed of sufficient promise by the Council on Pharmacy and Chemistry to warrant admission to New and Nonofficial Remedies. For a detailed description of benzyl alcohol, see the New and Nonfficial Remedies department of The Journal, Oct. 19, 1918, p. 1313.

Malaria Simulating Rabies.—A. Castellani (*Arch. méd. Belg.*, August, 1918, p. 145) describes an attack simulating rabies in a patient in Colombo, Ceylon, who had malaria. The diagnosis of rabies had been made. At the time Castellani saw him the patient was in an attack apparently of hydrophobia with a temperature of 102 F. The sight of water produced violent spasm of the larynx. An examination of the patient's blood during the paroxysms showed the parasites of malaria. Fifteen grains of quinin by intramuscular injection caused the disappearance of the symptoms of rabies in a few hours. Castellani says it was perhaps a hydrophobic syndrome of the nature of hysteria in a malarial subject, although the patient was not a neuropath and presented none of the stigmata of hysteria.

COMING EXAMINATIONS

Alaska: Juneau, March 4. Sec., Dr. L. P. Dawes, Juneau.

Arizona: Phoenix, April 1. Sec., Dr. Allen H. Williams, 219 Goodrich Bldg., Phoenix.

California: Los Angeles, March 17-20. Sec., Dr. C. B. Pinkham, State Capitol, Sacramento.

Colorado: Denver, April 1. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

Connecticut: New Haven, March 11-12. Sec. Reg. Bd., Dr. Chas. A. Tuttle, 196 York St., New Haven; Sec. Eclectic Bd., Dr. J. E. Hair, 730 State St., Bridgeport, and Sec. Homeo. Bd., Dr. E. C. M. Hall, 82 Grand Ave., New Haven.

District of Columbia: Washington, April 9-11. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

Idaho: Pocatello, April 1-2. Sec., Dr. Ray H. Fisher, Rigly.

Illinois: Chicago, March 3-5. Mr. F. C. Dodds, Supt. of Registration, Springfield.

Indiana: Indianapolis, Feb. 26-28. Sec., Dr. W. T. Gott, 84 State Capitol Bldg., Indianapolis.

Iowa: Iowa City, March 24-26. Sec., Dr. G. H. Sumner, Capitol Bldg., Des Moines.

Maine: Portland, March 11-12. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.

Massachusetts: Boston, March 11-13. Sec., Dr. W. P. Bowers, Rm. 501, No. 1 Beacon St., Boston.

Minnesota: Minneapolis, April 1-4. Sec., Dr. T. S. McDavitt, 741 Lowry Bldg., St. Paul.

Montana: Helena, April 1. Sec., Dr. S. A. Cooney, 205 Power Bldg., Helena.

National Board of Medical Examiners: Philadelphia, June 2-7. Sec., Dr. J. S. Rodman, 1310 Medical Arts Bldg., Philadelphia.

New Hampshire: Concord, March 13-14. Sec., Dr. Charles Duncan, Concord.

Oklahoma: Oklahoma City, April 8-9. Sec., Dr. J. J. Williams, Weatherford.

Rhode Island: Providence, April 3-4. Sec., Dr. B. U. Richards, State House, Providence.

California October Examination

Dr. C. B. Pinkham, secretary of the California State Board of Medical Examiners, reports the written examination held at Sacramento, Oct. 21-23, 1918. The examination covered 9 subjects and included 90 questions. An average of 75 per cent. was required to pass. Of the 34 candidates who took the physician's and surgeon's examination, 19, including 8 osteopaths, passed, and 15, including 8 osteopaths, failed. Four candidates, including 3 osteopaths, were licensed, their marks having been reconsidered and raised to passing grade. Fifty-one candidates were licensed through reciprocity. Two candidates received osteopathic reciprocity licenses, and 2 candidates received drugless healer reciprocity licenses. The following colleges were represented:

College	Year Grad.	Per Cent.

Book Notices

Physiology and Biochemistry in Modern Medicine. By J. J. R. Macleod, M.B., Professor of Physiology in the University of Toronto, Assisted by Roy G. Pearce, B.A., M.D., Director of the Cardiorespiratory Laboratory of Lakeside Hospital, Cleveland, and by Others. Cloth. Price, $7.50. Pp. 903, with 233 illustrations. St. Louis: C. V. Mosby Company, 1918.

This is not a textbook of physiology as usually understood, but a thorough review of those parts of physiology and biochemistry that bear most directly on general clinical medicine, with particular reference to the needs of the advanced students and of physicians. An enumeration of the different parts will give an idea of the scope of the book: the physicochemical basis of physiologic processes, the circulating fluids, circulation of the blood, respiration, digestion, excretion of urine, metabolism, endocrine organs or ductless glands, and the central nervous system. The first part discusses in lucid fashion the great physical and physicochemical principles of physiology; the exposition here given of osmosis, the laws of solution, gas laws, ionization, hydrogen-ion concentration, regulation of neutrality, and acidosis, colloids and ferments should prove of great interest and help to physicians and students in their efforts to advance their real understanding of disease. By far the larger part of the book is devoted to the divisions of physiology just indicated, which were selected for review because they have such wide application in the study of diseases. Physiology of the special senses, of muscle and nerve, and of reproduction is not considered, and there is no systematic discussion of immunology. It is a well written, well balanced, authoritative work, competent in every way to satisfy its purpose, namely, to facilitate the study, interpretation and treatment of disease in the light of physiology and biochemistry. The book has great potential value because it presents adequately the knowledge of these sciences that the physician can use to deepen his grasp of the nature and meaning of the phenomena of disease.

Pathologie de Guerre du Larynx et de la Trachée. Par E. J. Moure, Professeur à la Faculté de Médecine de Bordeaux, G. Liébault, Ancien Interne des hôpitaux de Paris, et G. Canuyt, Ancien Interne des hôpitaux de Bordeaux. Paper. Price, 26 fr. 50. Pp. 370, with 135 illustrations. Paris: Félix Alcan, 1918.

At the outset of this work, attention is called to the relative infrequency of injuries of the larynx, owing to the protection afforded it by the inferior maxilla and because of its free mobility. Contrary to organic lesions, the functional disturbances, as shown in changes of the voice, are exceedingly numerous. The topics discussed are taken up in this order: 1. The functional disturbances without any objective lesion: Here are noted mutism (dumbness), stammering and aphonia. The general treatment consists of rest, fresh air, hydrotherapy, faradization, and sometimes sedatives or suggestions. Massage of the larynx and education of the voice by means of exercises also were employed. 2. Extrinsic lesions of the larynx: In a summary of the anatomy of the nerve supply of the larynx, attention is called to the well known fact that the same nerve (recurrent) supplies both the constrictors and the dilators, that is, antagonistic muscles; the other nerve (superior laryngeal), although a sensory one, innervates the tensor of the cords. Lesions of these nerves from bullet and other wounds, producing the classical paralyses, and injuries to the esophagus, base of the tongue and hypopharynx are also described. 3. Wounds of the laryngotracheal tract, including fractures, lacerations, lodgment of foreign bodies, etc.: Considerable space is given to the study of cicatricial stenoses following injuries, especially those due to bullets and grenades. Attention is called to the fact that many of these lesions are more severe and more difficult of treatment and cure than similar ones encountered in times of peace. The action of toxic gases on the respiratory tract is also described, and the treatment outlined. 4. Surgery of the larynx and trachea: Tracheotomy, laryngotomy and thyrotomy are considered in detail as regards indications, contraindications, exact description of technic, and comparison of procedures in times of peace and those employed in emergencies of war. The remainder of the volume is taken up with the treatment of cicatricial laryngeal stenoses. The authors most emphatically endorse local anesthesia in the operative work for the correction of the stenoses. For the closure of tracheal fistulas the autoplastic method of Moure is used. The work closes with a list of case histories, together with illustrations showing the methods and results of the tracheal operative procedures. Written with usual French clarity and precision, this book gives a fund of valuable information, yet is not so bulky as to be wearisome.

La Cura Delle Ferite Toraco-Polmonari. Pneumotorace Artificiale Toracentesi Cura Dell'empiema. By Prof. Eugenio Morelli, Aiuto Alla Clinica Medica della R. Universita di Pavia. Paper. Pp. 181, with illustrations. Bologna: Licinio Cappelli, 1918.

This is a discussion of the subject of wounds of the chest, especially those in which hemothorax develops, with perhaps a later empyema. The causation—usually a bullet, shrapnel or shell splinter—is considered, together with the symptomatology and the results by various methods of treatment. The author had his schooling with Forlanini, whose work on the treatment of pulmonary tuberculosis, pulmonary hemorrhage, pleural effusions, etc., by means of artificial pneumothorax, is well known. It is not to be wondered at, therefore, that Morelli has applied the same principle to the treatment of this not infrequent accident of war. He has developed a technic that is accurately described in these pages and which, carefully carried out, has given surprisingly fine results, as shown by the case histories and the roentgenograms. The dangers of open pneumothorax as compared to closed are emphasized, a point that has been brought out by Duval and others of the French surgeons as well as by the Americans Graham and Mitchell, among others. The book seems to be a real contribution to clinical medicine and surgery, and its results, if confirmed by further trial, should be widely applied in civil as well as in military practice.

Infection and Resistence. An Exposition of the Biological Phenomena Underlying the Occurrence of Infection and the Recovery of the Animal Body from Infectious Disease. By Hans Zinsser, M.D., Professor of Bacteriology at the College of Physicians and Surgeons, Columbia University. With a Chapter on Colloids and Colloidal Reactions, by Professor Stewart W. Young, Department of Chemistry, Stanford University. Second edition. Cloth. Price $4.25. Pp. 585, with 30 illustrations. New York: The Macmillan Company, 1918.

The revision of this excellent work appears to have been a thorough one, especially of the chapters dealing with anaphylaxis, nonspecific serum and cell reactions, and specific therapy. The aim of the work is to present in detail the principles of the biology of infectious diseases, which must be mastered before these diseases can be studied and treated intelligently according to present practice, and this aim is accomplished in an altogether satisfactory way. The discussion of the origin of antibodies should be extended to include the results of the more recent work on this and related problems. That Sternberg was a pioneer in the study of phagocytosis should not be allowed to pass into oblivion. These and other shortcomings, none of which are in any sense of a serious nature, will be remedied easily when quieter days permit a more thorough and leisurely scrutiny of the literature.

War-Time Nerves. By Herbert J. Hall, M.D. Boards. Price, $1 net. Pp. 119. Boston: Houghton, Mifflin Company, 1918.

This little book consists of fifteen more or less disconnected essays by the author of "The Untroubled Mind." The first is an effort to answer some interesting questions regarding the relation of the war to the individual. "How do men get into it and why, and what is the reaction on those who stay at home?" he asks. What is the effect on the minds of the participants of the tremendous world war through which we have just passed? The writer, a neurologist of many years' experience, has "seen into the lives of a number of men who have enlisted or who have been drafted, who have come back from the service or who are waiting to go." He has also studied the lives of those who stayed at home. The net result, he concludes, "is all, or mostly all, good; and the greatest change is in simplification and a new idealism. We no longer need so many things to make us happy. There is in the air a sense of relief even in the face of dread and danger. . . .

War, even to those at home, is such an all-pervading, penetrating matter. It gets into the most sluggish blood, it activates the most torpid brain, it makes men alive, it makes them think." Other chapters on moods and obsessions, practical patience, justification, the middle course, truth-telling in medicine, the medicine of the spirit, symbols, and sleep are equally interesting and reassuring. Some of Dr. Hall's observations are worth remembering: "A sanatorium is a place where people, who, for any reason, are not able to live successfully at home, may find special conditions which make health and happiness possible." "People who work for a living rarely understand the debt they owe to monotony." "He is a wise physician who can tell the truth without spoiling it and his patient."

Précis de Dermatologie. Par J. Darier, Médecin de l'Hôpital Saint-Louis. Second edition. Cloth. Price, 18 francs. Pp. 864, with 195 illustrations. Paris: Masson et Cie, 1918.

Despite the war and its attendant demands on his time, Darier has been able to revise, and in many sections rewrite, his textbook on dermatology. To shorten the work as much as possible, he has dispensed with the bibliography, case histories, citations and academic discussions, and has limited himself to the essentials in descriptions, diagnosis and treatment of dermatoses. Much space is saved by the elimination of the customary chapters on the histologic and pathologic anatomy of the skin. The first part of the book classifies and discusses the dermatoses from the point of view of the fundamental pathologic process involved. In other words, the classification is made according to the essential lesions. The author admits that such a classification is open to many criticisms, but is of the opinion that it has advantages in the presentation of the subject to the beginner which far outweigh the disadvantages. In this opinion one may heartily concur. The second part discusses those diseases of the skin which may be considered morbid entities of definite etiology, and classifies them according to their nature and cause. No author has thus far evolved a classification of the dermatoses which is satisfactory to himself, much less to his colleagues, and every attempt at a classification is invariably criticized. Perhaps the one adopted by Darier is as clear and as workable as any other offered. Those diseases which have unknown etiologies, such as eczema, lichen planus and psoriasis, are not included in the second part, but are discussed in extenso in the first part, since the author considers them not as definite entities, but as pure syndromes. In this edition much new material has been added. Notwithstanding the high cost and the scarcity of paper, the publishers have maintained their standard of quality. A translation of this work into English should be welcomed by a large number of teachers and students of dermatology.

On the Nature of Things. By Hugh Woods, M.D., B.A., F.C.S. Cloth. Price, $2.50. Pp. 248. New York: William Wood & Co., 1918.

The author has taken as the title that of the poem by Lucretius written over 2,000 years ago in which the Roman poet and philosopher endeavored to set forth the ideas that prevailed in his day regarding matter, motion, space, light and time. Dr. Woods discusses such modern questions as heat, electricity, magnetism and chemical action. As he remarks in his preface, "Science has reared its structures, as builders erect towers, on foundations more or less solid, but without closely considering the exact nature of the foundations—how they were formed and from what." The rapid development of practically all branches of scientific knowledge has so enormously increased the amount that has to be learned in any one branch of science as to require a lifetime for the mastery even of a limited field, with the result that few men, however well advanced in the details of practical scientific work, have taken any time to familiarize themselves with the principles underlying all scientific knowledge. This is particularly true of physicians, in whose training instruction in both pure and applied science in physics, chemistry and biology is necessary. Very few physicians have ever given any attention to the fundamental principles underlying all scientific knowledge. Such a book as this, therefore, can be read with benefit by physicians, whether the author's views are accepted or not. Especially interesting is the chapter on chemical atoms and molecules in which is discussed the probable shapes of the atoms of the different elements and the influence of atomic form on chemical combinations. The chapter on light, which he regards as transverse ether waves, and electricity, which he considers to be longitudinal ether waves, is also illuminating and suggestive. The physician in the pursuit of technical professional knowledge has become far too narrow in his reading and thinking. Such books as the "Nature of Things" should be read by those physicians who desire to keep abreast of advancing scientific knowledge, and should result in a widening or our professional horizon.

Medicolegal

Power of Board of Health to Require Vaccination

(State v. Martin et al; Brazil v. State (Ark.), 201 S. W. R. 622)

The Supreme Court of Arkansas says that each of the two entitled causes involved the validity of a rule adopted by the state board of health, Dec. 3, 1917, and for that reason they were incorporated in one opinion. The first case it reverses and remands with directions to overrule a demurrer to the indictment of the defendants for permitting certain pupils in a school district to attend school without presenting a certificate from a licensed physician showing successful or recent vaccination, immunity from having had smallpox, or physical disability which might contraindicate vaccination, the demurrer being on the ground that the indictment did not charge a public offense against the defendants jointly or severally. In the second case the court affirms a conviction of defendant Brazil for sending his children to a school without presenting a certificate of vaccination or immunity from smallpox.

The court holds that there was no error in the fact that no proof was made in the Brazil case of the rule of the state board of health requiring a certificate of vaccination or immunity *therefrom by* pupils as a prerequiste to attendance on the school, as rules, orders and regulations made and promulgated by the state board of health will be judicially noticed by the court of the state. The court also holds against the contention in both cases that the board was not authorized by Act 96, Acts of 1913, to adopt and promulgate such a rule, because, while the board is not specifically authorized to supervise, control, suppress or prevent smallpox by isolation, quarantine or vaccination, or to adopt and promulgate any rule with reference to this particular disease, its isolation, control, suppression or prevention, the language of the statute is broad enough to include all diseases and all remedies, and specifically includes diseases that are infectious, contagious and communicable, and the power to prevent the entry into and spread of such diseases in this state. Moreover, while it is true that the board of health is not authorized to manage or control the schools of the state, either public or private, that power being conferred on other agencies, the prevention or spread of contagious or infectious diseases by preventing unvaccinated persons from associating with the schoolchildren and schoolteachers of the state in no way infringes on the constitutional right to attend the schools or the management and control thereof by schoolboards or directors. It would not be contended that parents and guardians could send their children to school unclad and unfed. Other reasonable health regulations are just as important as food and clothing. The mere fact that the will of the legislature is to be worked out through methods and details provided in rules and regulations to be adopted and promulgated by the board of health does not render the statute itself incomplete. The creation of boards of health for the purpose of preventing and controlling contagious diseases, and the right of the boards to adopt reasonable rules and regulations for that purpose, is not regarded generally as a delegation of legislative authority.

The necessity for, and reasonableness of, the regulations are largely within the judgment of the board. Every presumption is indulged in favor of the necessity of the rule, and courts will not interfere with acts of health authorities unless it is apparent that the rule is arbitrary. The existing conditions in the state at the time the rule was adopted warranted the adoption of such a rule, as it is commonly known that at that time smallpox was prevalent in the state, and that, unless preventive measures were adopted, a smallpox epidemic might result; besides, it was adopted during the period of the mobilization of the army quota of Arkansas, when soldiers were being transported in and out of the state in great numbers.

It is true that there is no American authority for compulsory vaccination in the sense of forcing one to submit his person thereto; but there is authority for penalizing one who refuses to comply with an order of law requiring vaccination. By reading the compulsory education act and the rule together, the net result is to enforce vaccination by penalty only. The act and rule can be read together so that both may stand, and should be read together, because it is quite clear that the legislature did not intend, in the passage of the compulsory education act, to repeal the health rule for preventing the spread of smallpox and other diseases.

Roentgenographic Injury Due to Hypersensitive Skin

(Hamilton v. Harris (Texas), 204 S. W. R. 450)

The Court of Civil Appeals of Texas reverses a judgment for $2,500 damages that was rendered in favor of plaintiff Harris for personal injuries alleged to have been inflicted on him by the negligent application of roentgen rays to his body by defendant Hamilton for the purpose of treating eczema. The court says it was alleged that the defendant was negligent because he failed to protect, with a blanket of lead, or a composition of rubber and lead, the plaintiff's body from being burned, such protection being usual and customary; that the opening in the protecting blanket was too large; that the current applied by the defendant was too intense; that he exposed the plaintiff to the current for too long a time; and that he left the room in which the treatment was administered during the application of the roentgen rays, whereas he should have remained and watched the effect of the treatment. The defendant answerd by general demurrer, general denial, and specially alleged in defense that the injury to the plaintiff was caused by the peculiar condition of his skin, which was alleged to be hypersensitive to roentgen-ray current, and that this idiosyncrasy of the plaintiff's could not have been discovered by the defendant prior to the treatment. The fact was that the plaintiff was severely burned by a roentgen-ray current while being treated professionally by the defendant, who was a practicing physician and an expert in treating skin diseases with the roentgen ray. The controlling issue of fact made by the evidence was whether the injury was caused by one or more of the acts of negligence alleged by the plaintiff, or whether the injuries were suffered because the plaintiff's skin was hypersensitive to the roentgen-ray current. Naturally whether or not the plaintiff did in fact have a hypersensitive skin was an issue.

The defendant's first and second assignments of error assailed the trial judge's general charge because it did not affirmatively submit to the jury the defense that the proximate cause of the injury was the hypersensitive skin of the plaintiff. The charge defined "negligence" to be the failure to exercise "ordinary care," and further instructed to find for the plaintiff if the jury believed from the evidence that the defendant was negligent as alleged and believed evidence that the defendant was negligent as alleged and that such negligence was the proximate cause of the injuries; otherwise to find for the defendant. The defense of abnormal skin made by the defendant's pleading and evidence was not affirmatively submitted. It was contended by plaintiff's counsel that the affirmative submission of the defense would have been a charge on the weight of evidence, inasmuch as the question of the plaintiff's hypersensitive skin was involved in the question of whether the defendant was guilty of negligence, and that there was no evidence that the plaintiff actually had the idiosyncrasy asserted. But, if credited by the jury, the testimony of the defendant himself and of five other physicians, as well as that of a physician who was the plaintiff's witness, was sufficient to authorize the jury to find that the plaintiff did have a hypersensitive skin, and that this peculiarity was the proximate cause of the injury. The court does not think the affirmative submission desired by the defendant would have been a charge on the weight of the evidence. A physician is not required to take precaution against a peculiar temperament or abnormal idiosycrasy of which he has no knowledge and for detecting which there is no means. The evidence showed that the defendant did not know of the plaintiff's hypersensitiveness, and that there is no way to ascertain such a peculiarity prior to the treatment. The court thinks the jury should have been told in appropriate language that, if it believed the proximate cause of the injuries to the plaintiff was his abnormal hypersensitiveness, but for which the injury would not have occurred, a verdict should be returned for the defendant. Wherefore the assignments of error are sustained.

But another assignment of error, which complained because the judge refused to submit an issue of assumed risk, is overruled, as there was no evidence that would authorize such a charge. There was no evidence that the plaintiff knew or ought to have known that the roentgen-ray treatment was dangerous, because powerful and insidious.

Use of Nonabsorbable Silk Sutures

(Linn et al. v. Peirsol (Calif.), 173 Pac. R. 763)

The District Court of Appeal of California, First District, reverses a judgment that was rendered in favor of Mrs. Linn in this action brought by her and her husband to recover damages for alleged malpractice. The court says that the defendant's main point on this appeal was that there was no showing of negligence on his part sufficient to warrant sending the case to the jury, and that therefore either his motion for nonsuit or his motion for a directed verdict should have been granted. The alleged negligence of the defendant, a physician, for which the plaintiff sought to recover, lay in the use by him in an operation of nonabsorbable silk sutures instead of catgut. The only testimony in the record to show that this was improper was contained in an answer to a single question propounded to a physician who was one of the plaintiff's witnesses, who testified that a careful surgeon would not use silk in the place where it had been used. On cross-examination he admitted, however, that, where a physician requires a ligature that will hold fast to prevent bleeding, he may with propriety use the silk, and he made it clear that his previous answer was based entirely on the conditions as he found them at an operation performed by himself six months after the operation by the defendant. The only other medical witness for the plaintiffs testified that the choice between silk and catgut is a matter of judgment in each particular case, and there was no testimony in the record to show that, under the conditions as they appeared to the defendant when he performed the operation, the use of silk was negligence. It appeared from the defendant's testimony that he had performed two operations on Mrs. Linn, that on the first occasion he had had trouble from hemorrhage as a result of the use of catgut, and that therefore he had used silk on the second occasion. It was true that the use of the nonabsorbable silk in the case at bar proved unfortunate, as the silk caused certain perforations of the intestine, which produced serious trouble; but it was clear that on the second operation the defendant was in a dilemma. The use of catgut had resulted in hemorrhage before, which he wished to guard against, and the use of silk might produce irritation. Under the circumstances, he should not be held liable for what was at most a mistake of judgment in weighing the probable consequences of the different methods that might be pursued. A physician is required to possess only ordinary skill in his profession and to use his best judgment in the exercise of that skill, and, if he complies with these requirements, he is not liable for the nonsuccess of his treatment. The defendant's motion for a new trial should have been granted, as the trial court's orders denying the motions for nonsuit and for directed verdict were erroneous.

Society Proceedings

JOINT MEETING OF THE CHICAGO MEDICAL AND CHICAGO PATHOLOGICAL SOCIETIES

Held Feb. 12, 1919

The President of the Chicago Pathological Society,
Dr. J. P. Simonds, in the Chair

Dr. J. P. Simonds: Yellow fever is of international importance and has an international bearing, and because of that fact the International Health Board of the Rockefeller Foundation, largely at the suggestion of General Gorgas, appointed a yellow fever commission to go to South America to study sanitary conditions on the west coast of Ecuador, particularly about Guayaquil. The Chicago members of this commission were Drs. Arthur I. Kendall and Charles A. Elliott. Dr. Kendall was for two and a half years chief of the government laboratory in the Canal Zone and had much to do along with General Gorgas in eradicating yellow fever from the Canal Zone.

National and International Relations of Sanitation in Ecuador

Dr. Arthur I. Kendall: Up to 1820, the vast majority of South American countries were under the subjugation of Spain. The United States has had in the past and will have in the future ever increasing interest in these countries. The greatest menace that these countries offer to the world at large is that which has to do with certain endemic diseases, and of these yellow fever and the plague are the most formidable. Yellow fever at present is endemic on the west coast of Africa and Guatemala, certain parts of Mexico, and the west coast of South America, south of Panama to the northern border of Chile, throughout the coast of the plain region, a distance of anywhere from 20 to 40 miles of the Andean plateau region. It is endemic on the east coast of South America, in Colombia, Venezuela, and possibly in the great land lying in the more western parts of Brazil. Yellow fever, therefore, is largely an American disease, and there are well authenticated histories of cases of yellow fever appearing as far north as New York and Philadelphia. In 1796 or thereabouts a rather extensive epidemic of yellow fever occurred in Philadelphia. Within the last few years New Orleans has suffered from yellow fever, and other southern cities at one time or another have been visited. In 1898 Havana, Cuba, enjoyed the somewhat doubtful honor of being called the pest hole of the American continent, and it was chiefly so regarded because of the prevalence of yellow fever there. In 1901 the last case of yellow fever occurred following the brilliant work of the American army. The mode of transmission of the disease was discovered by a commission headed by Major Walter Reed, and the practical measures suggested by General Gorgas (then Captain Gorgas) were put into effect. In October, 1906, the last case of yellow fever occurred on the Isthmus of Panama. As far as is known, there has never been a case since.

The great problem is to restrict the distribution of this disease until the time shall come when it will vanish from the face of the earth. Yellow fever is probably the easiest disease to conquer. The disease itself, so far as sanitation is concerned, spreads only in warm weather. It is transmitted exclusively through the agency of a particular mosquito, which enjoyed a large number of names prior to its discovery as the extrinsic host of yellow fever. The mosquito was known as the *Culex fasciatus* When it was found that this organism was responsible for the transmission of yellow fever from man to man, a little more careful scrutiny revealed the fact that the mosquito did not belong to the genus *Culex*, and a new genus, *Stegomyia*, was coined. Since that time the name has successively changed from *Stegomyia fasciata* to *Stegomyia calopus* and others.

The method of transmission of the organism of yellow fever appears to be very similar to that of *Plasmodium malariae.* The mode of transmission of malaria may serve as an illustration of the part the mosquito plays in the transmission of yellow fever, with which practitioners are familiar.

There is a latent period between the time the mosquito bites an individual and the time when that mosquito becomes infective for another individual. This period is roughly from ten days to two weeks. So far as is known, a similar cycle in point of time takes place in the transmission of yellow fever. The female mosquito bites patients with yellow fever, and then a period elapses during which that mosquito is quite unable to transmit the disease to another nonimmune host. This period coincides in point of time quite accurately with the period corresponding to the larvæ. There must be an extrinsic cycle in the mosquito which harbors the yellow fever organism quite as truly as there is an extrinsic period in the mosquito which harbors the malarial parasite. There is this difference between malaria and yellow fever: One attack of malaria by no means confers immunity or prevents infection. It predisposes to subsequent infection, or there is almost inevitably a series of relapses. It means that the individual infected with malaria may in successive intervals be a source of danger to other noninfected individuals. Yellow fever is a disease which allows the host to recover from the infection and to remain immune for all time. At least, this is so in the great majority of cases. Furthermore, the disease may be transmitted only during a particular interval, this interval elapsing between the time of the initial chill, which is quite common in yellow fever, and the period which is approximately seventy-two hours afterward. If this theory is correct, and experimental evidence suggests that it is, if every individual suffering from yellow fever should be screened and protected from mosquitoes at the time of the period just before the chill until the period of three or four days after the chill, yellow fever would cease to exist.

The methods of eradicating yellow fever are, first, to destroy the mosquitoes, which means the control of their breeding places, and also mosquitoes which are in the adult stage; to protect all febrile cases from the bites of mosquitoes during the three days or thereabouts in which persons may become infected, and finally to be certain that nonimmune individuals are kept out of unsafe areas. The method of exterminating mosquitoes is somewhat complicated in detail but simple in principle. It means careful drainage, inspection of all breeding places where the insects may grow, and the destruction of adult mosquitoes by fumigation.

The problem in Havana and in Panama for the extinction of yellow fever was somewhat different from that in South American countries, and particularly in Ecuador, where the work is now going on. In Panama and in Cuba the houses are, for the most part, of such construction that they can be fumigated quite readily, and one of the essential details of the elimination of yellow fever, as practiced in these places, was the careful fumigation of all of the houses at regular intervals in infected areas.

In Guayaquil, which is the principal point of infection at present, the structure of the houses is of such a nature as to render fumigation difficult. Earthquakes are common in Guayaquil; therefore the construction of buildings must be such as to safeguard the inhabitants from the danger of death by the collapse of buildings. The majority of the houses are made of frames which are joined in such a way that there is a certain amount of flexibility at the junction of the timbers, and these are covered with bamboo, which grows luxuriantly in the swamps, in the lowlands of Ecuador, and is of fairly large size.

Success in exterminating yellow fever and mosquitoes depends particularly on conducting operations quietly to prevent the mosquitoes from flying around. If unusual commotion is stirred up in placing these tents and putting them together, it will cause the mosquitoes to fly around. There is great probability that these mosquitoes fly from place to place; hence the question of fumigation is correspondingly complicated.

The mountaineers of Guayaquil are brought up in a country whose climate is much like our own. Yellow fever does not exist at the altitudes in which these mountaineers live; consequently they are quite as susceptible to the disease as are persons from temperate zones. In the endemic areas the probability is that the children get yellow fever before they are many years old, and therefore the disease in the adults of the coastal plain region is practically unknown. People, however, from the mountains, who come to the coast seeking employment or to embark for other countries and pass through Guayaquil or the coastal provinces, may become infected, and the influx of people from the higher levels keeps yellow fever alive, in spite of the fact that the number of foreigners who visit Ecuador are few indeed.

Ecuador is handicapped, as are other countries in which yellow fever is endemic, in their commerce with the world. Ecuador is a wonderful country. It raises everything from the finest fruits of the tropics, to those that are characteristic of temperate zones. It is near Panama; and since the Panama Canal is now open, many ships are required to carry provisions; consequently the elimination of yellow fever from Ecuador will give to that country a new life. If the country fails to rid itself of yellow fever, it will probably become bankrupt, and revolutions are almost certain to follow.

The International Health Board has charged itself with the duty of helping in international sanitation, and one of the groups in the International Health Board is the Yellow Fever Board, of which General Gorgas is chairman.

Some years ago General Gorgas and other yellow fever experts made a trip through the infected areas of yellow fever in South America and made known the prevalence of the disease there, and as a result of their trip and their deliberations, it was decided that it is feasible and possible to eliminate yellow fever from the face of the globe. If this can be accomplished, and Ecuador can be freed from yellow fever, the United States will be regarded in an entirely different light from what it is today.

Clinical and Pathologic Manifestations of Yellow Fever

Dr. Charles A. Elliott: Our clinical study was made in fifty consecutive cases of yellow fever. The histories elicited were fairly uniform. The first symptoms noted were a feeling of uneasiness, especially epigastric unrest, headache, backache, and aching of the extremities. Fever developed rapidly, often heralded by a chill or chilly sensations, which are frequently repeated. Nausea, and often vomiting, occurs repeatedly from the start, the latter usually bilious, although black vomit is noted by some of the patients as early as the second day. Fever, headache, backache, general muscular tenderness, and epigastric tenderness or pain, nausea and vomiting persist in various combinations until the admission of the patient to the hospital. A precipitous onset in uncomplicated cases, in which the patient gives a definite history of being well the day before the onset, is the rule.

In some patients who had been suffering from malaria for varying periods, a history of unusual symptoms, namely, sudden onset of nausea, vomiting, epigastric tenderness, headache, backache and persistent fever, was noted. This type of history of yellow fever developing during the course of malaria was present in four of thirty-nine cases in which reliable histories were obtained. In cases of this type the diagnosis was always uncertain until typical manifestations of yellow fever developed later, and most of these cases proved not to be yellow fever.

On admission the patient appeared restless and anxious, the face was flushed, the conjunctivae were injected, the gums were swollen, and they bled easily on pressure. Hemorrhages into the skin varying from 0.1 to several centimeters in diameter, usually irregular in outline, may occasionally be found on searching. Infected mosquito bites on the skin of the forearms or legs were frequently found. The mucous membrane of the mouth was congested. Herpes labialis was present in two cases. The lymphatic glands were not enlarged. The lungs were remarkable for being entirely free from findings expect during terminal hypostasis and pulmonary edema. The cardiac findings were usually negative. Occasionally a precordial systolic murmur was heard during the height of the disease, and rarely extrasystoles were noted. The abdomen was usually tender throughout, the epigastrium and liver edge being exquisitely tender. The liver was not definitely enlarged except in a few cases. The spleen was definitely enlarged only in those suspected of being malaria; it was not palpable in most of the pure yellow fever cases. Tenderness on pressure over the flanks was usually marked. The skeletal muscles were usually tender on pressure throughout the course of the disease.

During the second period of the disease the patients were relaxed, usually quiet, and appeared dried out, jaundiced, weak, and apparently very ill, but otherwise the physical findings remained about constant. The fever was relatively low, continuous, and of short duration. It reached its height on the first day, continued remarkably constant for three or four days, and then gradually dropped to normal by the fifth to the eighth day. The pulse was apt to be relatively slow during the fever course, showing a marked dissociation between the pulse and temperature curves at that time, although early and late, after the temperature has reached normal, the pulse follows the temperature curve. While a relative bradycardia of moderate degree is the rule, absolute bradycardia is unusual. A pulse of 50 or less was observed in only three of the series.

During the first few days of the disease the patient often complained of a sense of dyspnea, the only objective evidence of which was an occasional deep sighing respiration accompanied by a peculiar whistling expiratory note. Other than this, patients with light and moderately severe cases went through the entire course of the disease with apparently normal respirations. Jaundice was a constant, although variable manifestation in all cases. In general, it varied with the severity of the disease; in most light cases it was inconspicuous, although in some of these it appeared marked and out of proportion to the other manifestations of the disease.

The blood shows little that is characteristic. The white blood count averaged about normal, with a definite leukopenia of less than 4,000 in only nine cases. The high counts, from 49,600 to 13,000, were obtained in moribund, usually uremic, patients; but it is noteworthy that some comatose patients gave normal white counts. The hemoglobin was universally low, but three estimations exceeded 90 per cent.; ten were between 80 and 90 per cent., and estimations between 40 and 60 per cent. were common. Nothing distinctive could be detected in the blood pressure determinations, except that it was uniformly low, systolic pressures of 110 or less, and diastolic pressures of 65 or less being the rule.

Hemorrhage contitutes one of the distinctive manifestations of yellow fever as seen in these cases. The principal structures which bleed are the nasal and gingival mucous membranes, and the gastro-intestinal and genito-urinary tracts. A history of early epistaxis was present on inquiry in seven cases. Extensive epistaxis occurred later, namely, on the fifth to the twelfth day in twelve cases. Melena was present in thirteen of thirty cases in which this point could be determined; and in three, large quantities of fresh blood were passed. In general, in all severe cases there was bleeding during the second and third week of the disease, and in the light cases no bleeding at all. The administration of horse serum in six cases had no perceptible effect on hemorrhage. The urine of all yellow fever patients was extremely highly colored, varying from a dark yellow to olive green, the foam being always yellow. The amount passed varied from an average of 700 c.c. to complete anuria, which usually foretold death. Albumin began to appear as a trace on the second or third day, rapidly increased to enormous amounts, 3 or 4 gm. per liter during the second week, and then gradually decreased and finally entirely disappeared during the third or fourth week. In light cases, albumin and casts were present out of proportion to the other manifestations of the disease. Uremia occurred as a terminal condition in all fatal cases. The majority of the patients harbored intestinal parasites in the stools. Complications and sequelae were unusual. Parotitis occurred in two cases, phlebitis in one, and acute joint phenomena, such as pain and swelling of sudden onset, in three cases. Restitution progressed rapidly in all patients that recovered, although some were weak and many showed varying grades of jaundice at the time of discharge.

The greatest stress was placed on the following diagnostic points in the order named: 1. The fact that the patient was a foreigner and not a native of Guayaquil, or had recently arrived from the interior. The local physicians considered it practically impossible that a child born in Guayaquil should grow to maturity without having had yellow fever, and therefore was immune, and conversely, that a nonimmune adult could not live long in Guayaquil without having it. 2. A low, continuous fever course with relative bradycardia. A fever of 40 C. or over speaks against yellow fever. 3. Nausea and vomiting, black vomit being practically diagnostic. 4. Epigastric pain and tenderness, often intense from the first. 5. Rapid and progressive development of nephritis, albumin present as a trace on the second day, with from 1 to 3 gm. per liter on the fourth day. 6. Flushed and suffused face, injection of conjunctivae, and swollen and often bleeding gums. 7. The gradual and progressive development of jaundice, a trace seen on the conjunctivae as early as the third day.

The greatest difficulty occurred when yellow fever developed in those already infected with malaria. In children with yellow fever, as seen in this series of cases, the manifestations were the same as those in the adults.

In relation to the prognosis, it was difficult to foretell the gravity of a case. Those admitted early with much facial congestion, injection of the conjunctivae and swollen gums, who were restless and apprehensive, and showed some dyspnea, were considered as having the disease in very grave form, and usually died. Tachycardia is always considered grave. All uremic phenomena, such as air hunger, restlessness, delirium and coma, accompanied by a lessening of the output of the urine to anuria, were grave signs, although not always fatal.

Of the fifty patients in this series, nineteen died, a mortality rate of 38 per cent., which was considered about the usual rate in Guayaquil. The mortality rate of yellow fever of all patients admitted to the lazaretto from Jan. 1 to Aug. 1, 1918, was 44 per cent.

Little *treatment* was attempted beyond the employment of general principles applicable in all fevers. Little or no medication was given, and no conclusions can be based on our experience in this regard.

SOUTHERN MINNESOTA MEDICAL ASSOCIATION

Annual Session, held at Mankato, Jan. 20 and 21, 1919

The President, Dr. M. S. Henderson, Rochester, in the Chair

Some Old Hospitals of London: Treatment of Fistula in Ano and Hemorrhoids

Dr. William J. Mayo, Rochester: Among the most unique and interesting of the pioneer special hospitals of Great Britain is St. Mark's Hospital, founded in 1835, and built for the treatment of fistulas and other diseases of the rectum exclusively. It was here that the great Allinghams, father and son, worked and practiced the ligature operation for hemorrhoids. Fistula in ano has been well treated at St. Mark's Hospital for more than forty years.

Many years ago I was so fortunate as to become acquainted, by personal observation, with the methods introduced in St. Mark's Hospital for the repair of fistula in ano, and as a result, I can look back on a most satisfactory experience with this particularly annoying variety of infirmity. Goodsall pointed out that if a line was drawn transversely through the middle of the anus, all the fistulas lying anterior to that line would pass directly from the external skin opening to the internal opening inside the anal canal, and that all the fistulas posterior to that line would have their internal opening in the midline of the anal canal, posteriorly, no matter where or how many lateral openings, the so-called horseshoe fistulas, are present. In the anterior fistulas, therefore, the external opening will be found opposite the internal opening. An anterior horseshoe fistula, as Edwards remarks, is practically unknown. The cause of the curved or angular shape of the posterior fistulas, the external openings of which lie laterally and lead by a crooked passage to the internal opening posteriorly, is the arrangement of the coccygeal ligaments and muscles which protect the external tissues lying in the midline posteriorly and direct the pus laterally; the so-called horseshoe tracts and openings are thus formed. The treatment of the posterior fistula, which is the troublesome one, consists of carefully following the one or more external openings to the midline posteriorly where the fistulous tract leading to the internal opening just above the external sphincter will be readily exposed. At King's College Hospital, in 1862, Henry Smith originated the clamp and cautery treatment for hemorrhoids, a method we have used in hundreds of suitable cases with the utmost satisfaction. The hemorrhoid should not be trimmed away with the scissors, because, if the eschar pulls apart, the cut artery, which is most resistant, will bleed; the hemorrhoid should slowly be converted into an aseptic eschar protected by the desiccated tissues.

Acute Mastoiditis

Dr. Joseph D. Lewis, Minneapolis: Mastoiditis develops when a preexisting suppuration of the middle ear extends to the mastoid cells. When confronted with an impending or actual acute aural suppuration, efforts are at once directed to measures which are intended to terminate the purulent condition of the middle ear and prevent a further extension of the process to the mastoid cells by a free incision (myringotomy). Mastoidectomy, performed before complications supervene, is attended with little risk, even when the sigmoid sinus and dura are uncovered for inspection, as the danger of infection is slight, provided the dura is not wounded at operation. When operation is delayed until thrombosis of the sigmoid sinus, meningitis or brain abscess develops, the mortality is high, despite prompt surgical intervention. If acute purulent otitis media is allowed to continue until the condition becomes chronic, making it necessary to perform a radical mastoidectomy, there may follow loss of hearing.

Fractures Considered as Potential Deformities

Dr. M. S. Henderson, Rochester: Following a fracture in the region of the shoulder joint, the common disability is lack of abduction and external rotation; in the region of the elbow, lack of flexion, and in the region of the wrist there is the well known dinner fork deformity, with inability firmly to close the fingers. A fracture in the hip is prone not to unite unless adequate fixation is provided after the reduction. A supracondylar fracture of the lower end of the femur or an epiphyseal separation interferes with the proper transmission of weight through the joint surfaces, and limits flexion and extension. Pott's fracture not infrequently causes disability by the valgus produced by poor alinement for weight bearing. If the type of deformity that is apt to follow the particular fracture being dealt with is kept in mind, and if it is recognized that the deformity is potential, better results will undoubtedly be obtained by so directing the treatment as to guard against poor alinement of the fracture.

Open and Closed Treatment of Fractures

Dr. Archa E. Wilcox, Minneapolis: Whichever method is used, it is obvious that the best results follow, first, a complete reduction of deformity of the fragments; second, holding the fragments in place; third, obtaining osseous union, and fourth, the restoration of function of the affected part. No simple fracture should be treated by any other than the closed method until repeated and untiring efforts are made to reduce the fracture, checked and rechecked by the roentgen ray or fluoroscope, have failed. The Lane plate has rapidly lost favor with most surgeons who do much bone work. I have removed many more than I have put in, and even many of those surgeons who still believe in the use of these plates, and apply them, advocate their routine removal. In only rare instances, for temporary fixation, would I recommend them. The bone graft and the Parham band have been extremely useful. The main advantage of the Parham band is that it does not injure the bone and rarely, if ever, has to be removed, and with the carrier which I have devised it is easily applied.

In certain oblique fractures of the tibia which are very troublesome, I apply an intramedullary graft, which we have designated the "submarine" graft. The graft is cut with the twin saw. It is shaped to fit the medullary cavity at the site of fracture, and then replaced in the upper fragment and submerged into the medullary cavity and driven through the line of fracture into the distal fragment, the two fragments being held in a Lohman clamp. In three cases the clinical results apparently have been 100 per cent.

Placenta Praevia and Abruptio Placentae

Dr. M. J. Jensen, Minneapolis: Placenta praevia can be considered in two groups: cases in which labor has not begun and those in which labor has already started. The cases in which bleeding begins before labor may be treated expectantly by absolute rest and sedatives. The indications for this treatment are largely in the interest of the child. If sedative treatment has been tried and hemorrhage recurs while labor is not yet started, and in a case of a single profuse hemorrhage, active measures are indicated at once. In every case of placenta praevia and accidental hemorrhage, the strictest precautions for asepsis and thorough preparation, as for any surgical operation, must be carried out. In a certain number of these cases, cesarean section should always be performed: first, in primigravidae and other cases with sufficient pelvic obstruction to prolong labor seriously; second, in cases with a rigid and undilatable cervix, in which the indications suggest a prolonged labor, and third, in most cases of placenta praevia centralis and placenta praevia complicated by eclampsia. In accidental hemorrhage the method which empties the uterus in the quickest time possible without producing shock or injuring the soft parts, dilatation, version and extraction, is the method. Cesarean section should never be done as a routine measure until the child is viable and the mother is a good surgical risk.

Cerebellar Artery Occlusion.—The case reported by Hausman was one of occlusion of the left posterior inferior cerebellar artery with cardiac manifestations in a man of 48. The onset was gradual without loss of consciousness, but with a sense of giddiness, faintness and nausea, and a tendency to stagger occasionally to either side. This was followed a few days later by persistent hiccough and hoarseness. In view of the presence of glycosuria and a family history pointing in the same direction, diabetes, together with arteriosclerosis, was considered the etiologic factor. The symptoms resulting from this lesion embraced unilateral paralysis of the vocal cord and the left side of the face, with anesthesia of the pharynx and absent corneal reflex in the left eye; myosis of the left pupil and narrowing of the left palpebral fissure; peculiar response to the Bárány test; hemiataxy on the same side with alternate anesthesia of the left face and right side of the body. The sensory affection was of the dissociated type, pain and temperature sense being impaired, while tactile sensibility and muscular sense were intact. In addition, the patient presented an abnormal cardiac function. Various irregularities were manifested; bradycardia, auricular flutter, numerous extrasystoles and auricular fibrillation. Atropin administered over a long period was unable to influence the heart action in any way. With digitalis, however, a favorable reaction was immediately obtained. Hausman points out that the symptoms in this case, besides their value from a regional diagnostic point of view, have an important bearing on the relation of the vagus center to the cardiac cycle. It is this object which prompted a record of the case in detail.

Microscopic Brain Lesions in Dementia Praecox.—Southard discusses the idea of microlocalization, the antilocalizing views of psychologists, the anomalies in dementia praecox brains, makes a stratigraphical analysis of the cerebral cortex, and then points out the many effects of mental dissociation probably correlated with supracortical disease, the correlations of hallucinosis and catatonia with infracortical disease and the tendency to lobar and lobular focality of lesions. The microscopic data in four cases are presented under these heads, frontal, parietal and temporal. As far as the tissues of these four cases go, there is little or nothing inconsistent in the findings with the hypothesis that ordinary (nonphantastic) delusions are correlated with frontal rather than with otherwise situated lesions; but the supracortical type of delusions found in certain long-standing paranoiacs whose fine mental processes run in a quasi-normal manner, find no special correlation in any region, and the probable lines on which this problem is to be solved remain obscure.

As for auditory hallucinosis, the work seems to afford the expected correlation with temporal lesions. In one case, however, temporal lesions of considerable severity were not attended in life by hallucinations of hearing, but in this case there was also a severe supracortical disease of the temporal region, and it may be that for the production of hallucinations, some congress is necessary between the activation of the supracortex and infracortex, respectively. In previous work on this series, the brains had indicated a postcentral and superior parietal correlation for catatonia whose muscular hypertension was accordingly regarded as very possibly a kind of morbid kinesthesia. The present work suggests that the anatomic correlate is not merely to the postcentral and parietal regions, but still more specifically to the infracortical parts of these regions. Southard is in doubt whether these lesions are secondary in point of time to a noncell-destructive phase in the disease, or whether the lesions of which these microscopic effects are indicators began pari passu with the symptoms, that is, it remains a question whether it is a case of excess wear-and-tear process of cell mechanisms morbidly employed or whether the morbidity of neural function is an exact equivalent of the neuronic and neurologia morbidity.

Histogenosis of Multiple Sclerosis.—The four cases of multiple sclerosis on which Klingman's investigation is based were the usual cerebrospinal types. One patient died of acute mastoiditis; another died of pneumonia; one died in a convulsion and one from exhaustion following a number of epileptiform seizures. The average duration of the disease was ten years. All of the cases showed at necropsy a general adenitis with rather marked glandular enlargement in the bronchi and mesentery. One had healed tuberculous lesions in the left lung. The results of the examination of the brain and spinal cord of these patients are given in detail.

Subacute Multiple Sclerosis.—The patient who afforded the opportunity for Spiller's study was a male, aged 25. The symptoms began in February, 1915, with headache. In June, 1915, vision began to fail. In July, 1915, optic neuritis was observed. Weakness of the limbs developed gradually, with nystagmus, incoordination, vertigo, scanning speech, intention tremor and progressive impairment of gait until walking finally became impossible and mentality very feeble. Death occurred Dec. 21, 1916. Every section taken from any part of the cerebrum shows foci with lesions peculiar to this disease. The alteration in the cerebrum is very different from that in the spinal cord, and Spiller's findings confirm the statement of Marburg, namely, that cellular proliferation of glia is greater in the brain than in the spinal cord, and that the large glia cells are found more in the brain than in the spinal cord. The glia proliferation of the spinal cord is in large measure of the character of the overgrowth of glia seen in the replacement of nerve fibers from secondary degeneration caused by some lesion at a higher level; it is, therefore, chiefly fibrillar. In the cerebrum the glia proliferation is of a different character, it is chiefly cellular and is more recent than that of the cord. Mental failure usually does not precede the other symptoms of multiple sclerosis, it occurs later in the disease and the lesions producing it must be of late development. In Spiller's case the mental failure became pronounced and it is explained by the extensive alteration of the cerebrum. Therefore, the earlier changes of multiple sclerosis occur in the cerebrum. The lesions are usually less numerous in the cerebellum. The changes in the cerebrum in the case recorded by Spiller were in overgrowth of the glia causing a microscopic picture resembling that of a glioma. The relation of the foci to blood vessels has been asserted by some investigators, disputed by others—Spiller was unable to establish.

Syphilis of Nervous System.—In a series of 624 unselected cases of syphilis in all stages of the disease studied by Fildes and his associates, 18 per cent. had ten cells or over per cubic centimeter and 12 per cent. had from five to nine cells, inclusive, per cubic centimeter in the cerebrospinal fluid. In 80 per cent. of cases which had abnormal cerebrospinal fluid there was no clinical sign nor symptom of nervous disease, although twenty-nine cases had over 100 cells per cubic centimeter, nine had over 300 cells per cubic centimeter, and three had 1,000 cells or over per cubic centimeter. Many of the other 20 per cent. had symptoms so slight that they were of uncertain value in pointing one to central nervous system involvement. It was possible to detect slight but definite early changes in the eye-grounds of many of the positive cases in this series. That the changes in the cerebrospinal fluid were due to syphilitic disease of the central nervous system was demonstrated by the increase of cells, mostly lymphocytes but occasionally a few polymorphonuclears by the presence of a positive Wassermann reaction in the fluid, and by the fact that *S. pallida* can be demonstrated in the cerebrospinal fluid. Previous treatment has had no effect on the number nor on the severity of the abnormalities in the series. Intravenous treatment with arsenical preparations, during the period of observation, restored some patients to normal conditions; in nearly all it had a beneficial effect, but in a few cases the pathological processes in the central nervous system had not been checked even by repeated courses of treatment. The authors insist that the examination of the cerebrospinal fluid is indicated in every case of syphilis.

*Differentiation of Lactose Fermenting Anaerobes from B. Coli. R. L. Kahn.—p. 561.

Ozena and Distemper.—According to the cultural reactions and the agglutination and complement fixation tests made by Ferry and Noble there appear to be no reasons why Perez' bacillus should be confused with *B. bronchisepticus.* The organisms can be differentiated from each other by any one of several methods. The results of Horn and Victor's work with the complement fixation test were not corroborated by Ferry and Noble.

Standard Agar for Estimation of Bacteria in Milk.—The conclusions reached in this investigation by Sears and Case are that the present standard agar is not in itself a favorable medium for the growth of certain types of bacteria occurring in milk. The small quantity of milk added to the medium in plating 1 c.c. of a 1:100 dilution supplies the deficiency, but the amount added in plating the higher dilution does not do so. More consistent results are obtained if the dilutions of the sample higher than 1:100 are made in sterile 1:100 milk instead of in sterile water.

Simplified Confirmatory Test for B. Coli.—It is suggested by Kahn that in the conformatory test for *B. coli,* Endo slants be employed instead of Endo plates, and that the inoculations from the lactose fermentation tubes be made in the butt as well as on the slant of the Endo tubes, to permit aerobic and anaerobic growth. In the case of unknown waters, inoculations should be made from the fermentation tubes into Endo tubes after about fifteen hours incubation, even if there be no gas present in the fermentation tubes at that time. The advantages of the proposed modifications are: (1) The production of more typical colonies of *B. coli* on the Endo slant than of the Endo plate; (2) the detection of aerobic and anaerobic growth in the same test; (3) Endo agar tubes can be kept for three to four weeks without deterioration; (4) the inoculation from the presumptive fermentation tubes to Endo agar tubes before the production of gas in the former will often save several days time in establishing the presence of *B. coli* in an unknown water.

Differentiating Lactose Fermenting Anaerobes.—Anaerobic lactose fermenting organisms found in waters of the Southeastern area of the United States, appear to be unable to produce gas when grown anaerobically in Endo medium. In accordance with this finding, the differentiation of anaerobes from *B. coli,* is accomplished by Kahn as follows: Straight wire inoculations are made from the lactose fermentation tube showing gas, into the butt and on the slant of Endo tubes. After incubation (1) *B. coli* produces typical or semi-typical colonies on the slant and gas in the butt. (2) Anaerobes neither grow on the slant nor produce gas in the butt of these tubes. Employing the same medium, another procedure for the differentiation of anaerobes is described, wherein plates are employed instead of tubes.

Blood Volume in Wounded Soldiers.—The study reported on by Robertson and Bock includes a series of twenty-one cases of hemorrhage. Blood volume tests were made in fourteen cases, and with one or two exceptions the tests were performed repeatedly. The patients were of two types: those suffering (*a*) from the late effects of primary hemorrhage and (*b*) from secondary blood loss. Infection was present in the majority of instances. Blood volume tests made by the vital red method (Keith, Rowntree and Geraghty) on patients after hemorrhage showed a marked reduction in the total blood bulk. Not uncommonly the blood volume was less than 60 per cent. of the normal. The reduction after a certain point had been reached seemed to parallel the decrease in blood pressure. This relation of diminished blood volume to low pressure suggested a rough method of estimating blood volume from the change in blood pressure. By means of the blood volume and the hemoglobin percentage the actual amount of blood loss was determined. Cases of severe anemia showed a loss of as much as five sixths of the total hemoglobin. The effects of the different methods of transfusion and of injection of gum acacia on blood volume were negative. They restored the blood volume, only partially. Forced fluids by mouth brought about its complete restoration in a comparatively short time. The organisms did not restore its blood volume beyond a certain point when a further increase in it would, by dilution, have brought the hemoglobin percentage to a very low figure. In such cases a further increase of the blood volume occurred only when the hemoglobin rose. In cases with a low hemoglobin percentage as the result of a restoration of the blood bulk, an abnormally high blood pressure appeared, which continued until the hemoglobin percentage again increased.

Accompanying the low blood pressure seen shortly after hemorrhage was a well marked difference in hemoglobin per cent. between capillary and venous blood, with a relative concentration on the capillary side. As compensation occurred and blood pressure rose this difference lessened until the two readings were identical, indicating an even redistribution of the red blood cells. Reticulated red cell counts made in these cases showed that a marked bone marrow stimulation occurs after hemorrhage. The patients who were put on forced fluids, with consequent rapid restoration of blood volume, showed a much higher percentage of reticulated cells than those in whom no attempt was made to increase the amount of fluid in circulation.

Restoring Blood Volume by Use of Forced Fluids.—In many instances dilution of the blood occurs very slowly when the patient is recovering from hemorrhage. By putting such patients on a large fluid intake by mouth and rectum, Robertson and Bock found that their blood volume can be increased promptly and greatly. More than this, forcing fluids in cases where the amount of bleeding is difficult to estimate on account of the presence of a high hemoglobin percentage is of distinct value, since the dilution of the blood which results serves to show the extent of the hemorrhage through the drop in hemoglobin that it entails. With a total hemoglobin reduced to 25 per cent., or under, transfusion is needful. With the total hemoglobin above 25 per cent., the chief need is for increased blood volume, and if the patient's condition demands an immediate and large addition of circulating fluid, gum acacia solution should be given. If the condition is not so urgent, forced fluids by the alimentary tract are indicated.

Pressor Effect of Epinephrin.—Rous and Wilson found that ether anesthesia has a marked influence in diminishing the pressor response to minute amounts of epinephrin injected directly into the circulation. Hemorrhage also acts to lessen or abolish the response, and to a degree directly proportional to the lowering of the blood pressure it causes. In the exsanguinated animal an amount of epinephrin three or four times that sufficient to produce a pressure rise of 10 to 15 mm. of mercury, under normal conditions, may be entirely without effect. The response to large doses, on the other hand, is uninfluenced by ether or hemorrhage. These facts have a practical bearing not only on the employment of epinephrin to tide over collapse, but on its possible utilization in the future to raise a low blood pressure to the normal height and maintain it during a considerable period. The amount of epinephrin which under normal conditions will suffice to bring up the blood pressure may have little or no effect on an etherized individual or on one who has lost blood.

Bacillus Egens Found in Gas Gangrene.—The bacillus described by Stoddard occurred in a fatal case of gas gangrene, occurring in a wounded soldier. The cultures were derived from infected muscle at a considerable distance from the wound surface, and no other anaerobes were present in the muscle. The bacillus proved markedly pathogenic for guinea-pigs, producing extensive muscle lesions from which pure cultures of the bacillus were always obtained. Thus, in Stoddard's opinion, there is good proof that the bacillus found was the responsible agent in the fatal human case. Morphologically, the similarity of the bacillus to *B. welchii* is marked. Its cultural reactions are such, Stoddard says, that in a mixed culture with *B. welchii* it would escape notice, unless the most careful plating were done. When it has once been isolated however, it is culturally and pathologically distinct. Since the bacillus appears to be a new species, Stoddard has given it a new name. It differs from *B. welchii* by lack of fermentative powers; from *B. fallax* by lack of motility; from *B. oedematiens* and other anaerobes by lack of spore formation and of proteolytic power. Therefore, the name "egens" has been chosen.

Causative Agent of Seven Day Fever.—The authors analyze twenty-six cases of seven day fever seen by them in which the *Spirochaeta hebdomadis* was found both in the blood and urine.

Differentiation of Streptococcus Hemolyticus.—The work done by Avery and Cullen showed that the hydrogen ion concentration at which the human strains of *S. hemolyticus* cease to grow is different from that which limits growth of hemolytic cultures from bovine sources. This study comprises 169 strains of *S. hemolyticus,* of which 124 were of human origin. In the majority of instances these organisms were isolated from the throats, sputum, blood and long lesions of men suffering from postmeasles bronchopneumonia, or from the throats of those intimately in contact with these patients during an epidemic of pneumonia at one of the camp hospitals. In addition, several strains of *S. hemolyticus* from erysipelas, postpartum sepsis, meningitis and cellulitis have been included. It appears that the final hydrogen ion concentration of human and bovine hemolytic streptococci is a constant and distinctive characteristic of these organisms. The human type of *S. hemolyticus* reaches a final hydrogen ion concentration of p_H 5.2 to 5.0, and the bovine type of p_H 4.5 to 4.3. By the method described, by the authors, 95 per cent. of all the strains examined were accurately and rapidly classified by the determination of their final hydrogen ion concentration in 1 per cent. glucose broth.

War Deafness and Its Prevention.—Guild's previous articles on this subject were abstracted in The Journal, Oct. 27, 1917, p. 1472, Feb. 9, 1918, p. 418, and April 13, 1918, p. 1121. This paper describes the condition of the labyrinthine parts in the middle ears previously studied. Summarizing these articles from a practical viewpoint, these tests indicate that the measures tested may be divided into two definite groups on the basis of their efficiency in preventing the passage of the force of the detonation waves used; the variations within each group are less decisive. In the more efficient group are the Scientific Ear Drum Protector "Tommy," the Mallock-Armstrong Ear Defender, cotton soaked with glycerin, cotton soaked with petrolatum and the wax cone of the Italian navy type. In the less efficient group are dry cotton, the Elliott Perfect Ear Protector, and the Wilson-Michelson device.

Decomposition of Arsphenamin.—Rieger claims that commercial arsphenamin may contain an arseniureted methyl compound, which decomposes either in the ampule or in solution, with liberation of arsenous oxid or a cacodyl-like substance. Some preparations betray the presence of the arsine by their garlic-like odor when dissolved; others develop it only after having stood in solution for hours. According to the amount that may have accumulated, the dosage and the idiosyncrasy of the patient, a reaction marked by fall in blood pressure, dyspnea and cyanosis may occur. Once the drug has been injected, the occurrence of subacute or chronic arsenic poisoning is determined by the margin that exists or may be made to exist between its elimination and its reduction by the tissues. There is evidence that this reduction to metallic arsenic occurs too readily for safety with present commercial preparations of arsphenamin. Rieger suggests that the preparation of a neo-arsphenamin without the use of methyl alcohol and a study of its therapeutic behavior would do much to prove or disprove the hypotheses advanced by him.

Rôle of Tuberculosis in Dementia Praecox.—This study is based on 108 cases which have come to necropsy. The cases were thoroughly reviewed by Gosline and all those were discarded which gave a history of alcohol, syphilis, or infectious disease coming on at the onset of mental signs, or which gave anatomic evidence of syphilis, or which mentally might be classed under any other category than dementia praecox, or in which there was some doubt as to the diagnosis. Discarding all doubtful cases, there were left thirty cases which were retained as a basis for this study. Of this number twenty-one persons died of tuberculosis of various organs, chiefly of the lungs. One died of pulmonary abscesses from which tubercle bacilli were discovered in the smear. These twenty-two cases thus make a percentage of 73.3 dying of tuberculosis. The thirty cases showed something more convincing as to the connection between them and tuberculosis than the mere incidence of death from tuberculosis. Seventeen cases, or 56.6 per cent., showed a connection so apparent that they are considered by some to belong to the toxic-infectious group. Thirteen cases showed a course which may in a fairly definite way be considered to be bound up with a clinical or anatomic tuberculosis. Tuberculosis was demonstrated anatomically in all of them and the anatomic picture was the one to be expected from the course of the mental picture, the physical signs, such as weight and the subjective symptoms, and from the temperature chart. Hence, it is evident that there is a definite group of cases of dementia praecox in which tuberculosis may be considered to be a causative factor and, possibly, the causative factor. Gosline suggests that special complement-fixation tests on the blood and spinal fluid and special cultural methods applied to such cases should yield a high percentage of positive results and give an added advantage in early diagnosis.

Study of Buried Bone.—Numerous experiments are recorded by Cowan and Ely. It seems that a patella, or the fragment of another bone, imbedded fresh in the muscle of the animal from which it was removed, has a tendency to disappear, but does not do so for a long time. Its structure becomes less dense. The bone tissue itself may be replaced by fibrous tissue, especially at or near the circumference, or it may be absorbed. Absorption is the rule in the interior. Occasionally, typical rarefying osteitis by osteoclasts is seen. More frequently the process seems to be one of simple absorption, "halisteresis." The method of absorption is often difficult to determine, for about many of the trabeculae there are no giant cells, no leukocytic infiltration, and no increased vascularity of the marrow. Many of the cells disappear early from the bone. Others stain well after the expiration of a long time. Death of bone is the rule. A patella, with a complete investment of bone and cartilage, does not resist absorption better than a bone fragment whose marrow is exposed to the surrounding tissue. A blood supply is established in the marrow of the buried bone. The marrow has a tendency to become fatty and fibrous, though patches of lymphoid tissue may persist. It is engorged in animals who have died with an acute infectious disease, as is the marrow of normal bone in such circumstances. In other words, it is functioning as marrow. Cartilage becomes eroded at its surface, and is replaced by fibrous tissue. Sometimes it appears completely in areas. Its cells often stain well after a long time. Sometimes they die after a shorter time. The buttress underneath the cartilage almost always disappears early. Judging from appearances, the buried bone becomes smaller in size. Roughly, the changes in bone and cartilage are the same as those seen in arthritis of Type I, atrophic, or proliferative arthritis.

Treatment of Chronic Gunshot Wound Osteomyelitis.—A considerable number of these cases were treated by Eikenbary by open operation. He never uses the curet. The focus of disease is chiseled out and the wound is firmly packed with plain sterile gauze strips. No antiseptic gauze was ever used. At the end of twenty-four hours, the original packing is removed and the wound lightly packed with the same type of sterile gauze. Within a few days the packing merely extended through the soft parts. The whole aim of the operation is: (1) to get rid of all necrotic bone; (2) to avoid leaving any cavity at all; (3) to avoid spicules, rough areas, etc. Almost without exception, these cases healed within four weeks. Many were healed within three weeks, and in one instance healing was complete in two weeks.

*Absorption of Drugs and Poisons from Ureter and Pelvis of Kidney. D. I. Macht.—p. 481.

Absorption from Renal Pelvis in Hydronephrosis.—According to Burns and Swartz, absorption takes place from the renal pelvis after complete ligation of the ureter and in long-standing hydronephroses. The path of absorption is by way of the tubules and through the capillaries of the glomeruli. The rate of absorption is prolonged, especially in case of hydronephrosis. During the first twenty-four hours the rate of absorption is frequently the same in long-standing hydronephroses as in the acutely distended pelvis.

Provocative Vaccine in Gonorrheal Urethritis.—Two small doses of vaccine, on successive mornings, are given by Pearson. In none of his cases did the vaccine produce a general reaction nor was any discomfort caused to the patient and no complications followed its use. On the morning of the first day a dose of 3 million of polyvalent gonococcal vaccine is administered subcutaneously, and at the same time the seminal vesicles, prostate and Cowper's glands are massaged thoroughly to liberate any toxins confined in them. The patient is then instructed to hold his urine from midnight of that night until a smear is taken the next morning and to do the same for each successive night until four smears have been obtained. On the morning of the second day, a dose of 5 million of the vaccine is administered. Should the case still be infected with the gonococcus, a positive smear may be obtained on one of the four mornings. Should there be no infection with the gonococcus, the smear will remain negative for that organism. One hundred consecutive cases are tabulated. The provocative vaccine gave a reliable result in 96 per cent. of cases, but Pearson advises that it should not be relied on solely; it should be used in conjunction with other routine tests. Besides being valuable to determine when a patient is cured, it is useful to differentiate between specific and nonspecific urethritis. Its use renders unnecessary the irritation of the urethra produced by strong provocative injections of chemicals.

Absorption of Urine from Colon.—In the case studied by Cecil and Cummings uretero-intestinal anastomosis resulted from traumatism. Marked toxic symptoms resulted from the absorption of urine from the colon. Nephrectomy was followed by cure.

Absorption of Drugs and Poisons from Ureter.—Aconitin, cocain, apomorphin and potassium cyanid Macht found to be drugs or poisons that are absorbed easily through the walls of the ureter and the kidney pelvis. These findings are of some practical importance and should be borne in mind by the practical urologist inasmuch as various drugs such as silver compounds, thorium, etc., are introduced into these organs for diagnostic and therapeutic purposes.

Use of Calomel in Treatment of Influenza.—During the recent epidemic some rather striking results were obtained by Mann from calomel therapy in a few cases that were indirectly under his supervision. After observing over 3,000 cases of the so-called "Spanish influenza," it appears to Mann that the disease is essentially a toxemia. Detoxication is one of the many functions of the liver. Acting on the assumption that the toxemia might be combated to some extent by stimulation of the hepatic function by mild doses of calomel, the following procedure was adopted as a routine: (1) Calomel, ¼ grain, give every half hour for six or eight doses, followed by a mild dose of magnesium sulphate in the morning, or if the patient was very ill, an enema was substituted. (2) Calomel, 1/10 grain, was then given four times a day for three or four days. In many cases where the fever tended to show secondary rises, or to remain high, the administration of 2 grains of calomel in fractional doses was repeated with rather good results. In some cases nausea is caused by these fractional doses of calomel and, if so, it should be discontinued temporarily although in many cases nausea and vomiting is one of the pronounced symptoms of the disease. The wards which first adopted this treatment presented a much better appearance and a lower mortality rate than the other wards. Also, since the adoption of this therapy as a routine, the ward medical officers are unanimous in their opinion that beneficial action has resulted from its use. The best results were obtained in the early treatment of cases by this method. The cases of influenza that had progressed for some days failed to respond to calomel as readily as the incipient cases.

Laboratory Diagnosis of Tuberculosis.—The position of the laboratory in the diagnosis of tuberculosis is discussed by Gradwohl. He says that it is strikingly useful in such diagnosis; but that its usefulness is in direct proportion to the industry and intelligence of the clinician who uses it. In other words, it will serve well the physician who knows how to run down the focus when he has positive findings, and who knows how to weigh in the balance the negative results, that are inevitable in all specific microbic conditions at certain times and under certain conditions. The laboratory can aid the clinician in his diagnosis of tuberculosis of the upper respiratory tract, skin, joints, serous cavities, bones, digestive and genito-urinary system by means of the microscopic identification of the tubercle bacilli in sputum; its rare demonstration in pleuritic fluid, joint fluids, spinal fluid; its frequent demonstration in pus and discharges from the intestine; its occasional demonstration in the urine; better by animal inoculation in all but the pulmonary cases; by cultivation directly from sputum, and other tuberculous discharges from all points of infection by the Petroff method; by subcultures from lesions in inoculated animals; by blood cultures in the less common forms of acute miliary tuberculosis, and by complement fixation tests in tuberculosis anywhere in the body; likewise by tuberculin reactions of all classes of infection.

Traumatic Myositis Ossificans.—Abstracted in The Journal, June 15, 1918, p. 1889.

Pneumatic Tool Effects on Nervous System.—The case of the pneumatic hammer as used in the stone industry is the subject of Barnes' paper. Within the past two years complaints of ill effects from the use of the hammer have become prevalent in the Indiana belt. It has been claimed that the use of the hammer produced in the men a disease condition affecting the nervous system and leading even to paralysis, insanity or other form of complete incapacitation. So far as Barnes' study was concerned, the men using the pneumatic hammer in limestone were found to be in very good general health, none of the group examined showing any constitutional disease of any system, their troubles supposedly from the hammer being limited to a disturbance of the function of the left hand, which is commonly known as "white fingers" or "dead fingers." As a general rule, this condition occurs shortly after the men first go to work in the morning or until they have "warmed up." It occurs also during cold weather when the hands are exposed otherwise than in working. By swinging the arms or rubbing the hands the condition may be made to disappear, and when the hands are warmed the pallor rapidly gives place to diffuse flushing and reddening. Mental disease was not present in any subject examined, nor was there any physical disease which could, in any way, be attributed to the occupation.

After-the-War Problems of Medicine.—As Wile sees it, the after-the-war problems of medicine are those which tend to improve the organization of medical systems for developing public health and public health officers. Every physician of the future in his private capacity may attend individuals, but in his public capacity as a citizen doctor he will be an instrument to preserve the public health. All the problems that have developed from the war are those which contemplate making possible and tangible medical cooperation rather than individual competition. Attention is to be focused on the mass rather than on the unit. Private personal health will be appreciated as a constructive phase of public health. The medical profession, in contemplating the enormity and variety of its problem, has an opportunity to rise to a higher plane of activity and service than it has even known. Wile says that it is safe to conjecture that the opportunities will not be cast aside, nor will the end-results be dissonant with those claims for service which have been the basic principle of a profession that claims its origin in divinity and first functioned through a priesthood.

Dangers of Artificial Pneumothorax.—Stivelman claims that sudden collapse during the operation for artificial pneumothorax is very infrequently due to causes other than pleural shock. Air embolism, puncture of the heart and cocain poisoning are very rarely met with, and spontaneous pneumothorax, although it may occur, is easily diagnosticated and can usually be prevented. Pleural shock occurs as often after careful anesthetization of the pleura as when no anesthetic is used at all. It is impossible to foresee it. When it occurs in a severe form it may be fatal but in the vast majority of cases recovery occurs more or less promptly. Amblyopia, aphasia and other distressing symptoms subside very rapidly. Stivelman holds that attempts at refilling, according to Forlanini, are contraindicated if the attacks reappear in subsequent sittings.

Pathogenicity of Protozoon Parasites.—Fifteen cases of protozoon infection are reported by Hinkelmann. He claims that infection by the ameba, the balantidium coli, the cercomonas hominis and the organisms of the trichomonas group may become generalized through the entrance of the organism into the circulation, after which metastatic lesions in various parts of the body may result. The kidneys are especially prone to the infection, on account of their function in the process of elimination. Remnants, or whole and living organisms, may appear in the urine, and in the case of amebiasis this is a valuable diagnostic point. The metastatic lesions, especially in amebiasis, may be manifested directly and apparently as the primary condition. Protozoon parasites may be recovered alive and active from the blood through the method of hemolyzing freshly drawn blood with distilled water and centrifuging. The balantidium coli may be recovered from the blood in culture by placing the blood into sterile distilled water in the proportion of 1 c.c. of blood to 200 c.c. of water. Amebiasis may be suspected in all cases of obscure fever showing a striking difference between morning and evening temperatures, with the leukocyte count remain steadily at about 12,000, regardless of the presence or absence of diarrhea or any suggestive intestinal symptoms.

In semitropical countries, sudden pain in the abdomen with rigidity and fever is not always indicative of appendicitis, but may be caused by an abscess formation due to protozoon metastasis: especially if the leukocyte count rises above 12,000 and does not agree at all with the acuteness of the case. Chronic languor, pallor, emaciation with an eosinophilia and a stubborn constipation, many mean a swarming infection of the trichomonas intestinalis high up in the intestinal tract. Skin eruptions may be caused by protozoon invasion of the blood. These protozoon parasites appear, in varying degrees, to have everything in common. They act alone, or in conjunction with one another; and conditions which predispose an infection by one do so for the others as well. Immunity cannot be established, but a valuable amount of resistance appears in all individuals, which combats the invasion in the beginning. When this resistance becomes broken down, the case becomes chronic in some form or other; or the patient succumbs to an overwhelming proliferation of the invading organism, in an acute atack, depending on with which one of the group he has become infected.

Medical Treatment of Gallbladder Affections.—For the constipation or irregular stools, the following combination has afforded much relief in Nile's experience: fluidextract senna, 2½ drams; aromatic fluid extract cascara, 2½ drams; fluid extract podophyllin, 1½ drams; sodium and potassium tartrate, 2½ drams; simple syrup, 7 drams. One teaspoonful is taken night and morning as needed. For the gastric flatulence, Niles recommends the following carminative prescription; compound spirits lavender, 2 drams; zinc sulphocarbolate, 15 grains; magmae magnesii, 2½ ounces; water, enough to make 4 ounces. One teaspoonful is taken after meals, and repeated as needed for gas. For the general toxic symptoms, due probably to the lack of normal bile in the intestines, he has employed with satisfaction small doses of mercury protoiodid (1/10 to 1/3 grain), three times daily. Occasionally this drug produces intestinal cramps, or griping, so that the dose must be reduced, and in rare instances the teeth may become sensitive. As a biliary disinfectant, Niles has employed the following capsules: sodium succinate, 1½ drams; sodium salicylate, 1½ drams; sodium glycocholate, 45 grains; sodium taurocholate, 45 grains. Divide into sixty capsules and take two capsules three times daily, an hour and a half after meals, with a full glass of water. If the capsules are objectionable, the same ingredients may be dissolved in simple elixir, to which may be added a small amount either of compound spirits of lavender or of caramel. The polyvalent combined bacterial vaccines are sometimes worth while, but are not always dependable.

If the gastric secretions be markedly diminished and the duodenum become irritated, thus setting up a diarrhea, pancreatic preparations, liquor pancreaticus combined with alkalies, are of service. For the unpleasant itching there may be used ablutions with diluted vinegar, lemon juice, spirit of menthol or phenol. There also may be dusted on, the following powder: powdered camphor, 1½ drams; zinc oxid, ½ ounce; starch, 1 ounce. The diet should be free from irritating constituents, consisting principally of carbohydrates. But little fats should be permitted, and those easily emulsified, such as butter and milk. Other neutral fats cannot be cared for in the absence of a normal biliary flow; neither is it well to allow much meat, for excessive intestinal putrefactive processes may easily develop. Fruits, minus their rough or woody constituents, are generally advisable. The meals should be small, but frequent, and the general nutrition should be supported as far as possible. Hydrotherapy, when intelligently administered, is a valuable adjunct.

Evils of Spit and Spitting in Spreading Disease.—Taliaferro outlines what he terms a "catechism" on "spray borne diseases," and suggests that schoolchildren be taught thoroughly on this subject on the basis: "Teach the child and you teach the whole family." Taliaferro claims that 386,030 deaths occur annually from spray borne diseases.

Suspension for Laryngeal Work.—Lynch has the patient lie flat on the table with the head extended. The mouth is opened wide by placing an ordinary mouth gag in the left angle of the mouth; and this is steadied by the assistant who has only to keep the head extended in the middle line, there being no need of support, since the head is resting on the table.

*Abnormal Naughtiness in Normal Children. J. Thomson.—p. 269.
*Case of Muscular Spasm in Child. R. C. Jewesbury.—p. 269.

Ruptured Aortic Aneurysms in Childhood.—A case is recorded by Bronson and Sutherland in which death was due to the rupture of a fusiform aneurysm of the ascending arch of the thoracic aorta in a child, aged about 6 years. The aneurysm apparently followed a partial stenosis of the aorta between the insertion of the ductus arteriosus and the left subclavian artery. That this stricture was a congenital anomaly was supported by the presence of a diaphragmatic hernia, subluxation of the joints, and defective cranial development. A brief discussion of the etiology of aneurysms in children is given. From the literature are summarized two instances of aneurysmal dilatation due to partial stenosis of the thoracic aorta, also five cases of aneurysms apparently due to congenital anomalies in the structure of the ductus arteriosus. In two of the latter cases, rupture caused death. Also on record are seven reports of death following rupture of aneurysms of the thoracic aorta in children, one case of rupture of the aorta without aneurysm, and two cases of rupture of aneurysms of the abdominal aorta.

Abnormal Naughtiness in Children.—A morbid exaggeration and perversion of the natural desire which all children feel for notice by their elders, is held by Thomson to be the cause of abnormal naughtiness in children. These cases are of essentially the same nature as those of "moral imbecility" in children who are in some degree mentally defective. The proper lines of treatment are clear enough, and when carried out consistently and thoroughly are rapidly and completely successful. They may be summarized as follows: (1) All severe corporeal punishment must be stopped—it never does any good. (2) Nobody must ever appear shocked, amused or even surprised at anything a child does. (3) His misdeeds are never to be alluded to, much less described, in his presence; and, lastly, he should be noticed and encouraged in every way when he is good and altogether ignored when he is naughty.

Case of Muscular Spasm in Child.—At the age of seven Jewesbury's patient began to suffer from weakness and wasting in the muscles of both legs. This condition gradually progressed, and she developed such a marked degree of talipes equinovarus that double tenotomy of the tendo Achillis was performed. The condition gradually recurred and the legs became very stiff when she attempted to use them, and walking became exceedingly difficult. Subsequently, about eighteen months after the legs began to be affected, she developed a similar loss of power with stiffness in the muscles of both arms and hands, and also in the muscles of the neck and spine. Any attempt to carry out a definite movement with the arms was made in a jerky way, rather like a child suffering from chorea. In grasping any object all the voluntary muscles of the body were thrown into a state of spasm. She appeared to have a certain amount of control over this spasm, and it was always much more marked when she was at all excited or agitated. She also had a persistent torticollis with a certain amount of spasm of the spinal muscles. The facial muscles were unaffected. No tremors or athetosis were present. The reflexes, both superficial and deep, were all normal; the knee jerks were only difficult to obtain when the muscles were in a state of spasm. The plantar reflex was flexor on both sides. The cranial nerves were normal. Sensation was unaffected. The blood gave a negative Wassermann test. The case seems to be an example of "dystonia musculorum deformans" (Oppenheim) or "progressive torsion spasm of childhood."

Climacteric in Men.—Attention is directed by Rankin to the fact that while the climacteric period is a well recognized event in women, it is not so generally appreciated that men go through a similar readjustment of tissues, though after a less dramatic method, and probably at a somewhat later age, from seven to ten years later. A similar liability to the awakening of latent proclivities exists, and there would seem to be, at that period, as in women, an upset of tissue equilibrium conducive to the establishment of pathologic conditions. The immediate counterpart in man of the ovarian changes in women is probably to be found in the structural alterations which then become established in the prostate gland. Acute illness occurring within the limits of this critical time is attended with more than average risk, the protective powers of the body being just then apparently less able to resist germ or toxemic invasion. Among the many ailments that may assert themselves at the climacteric, three are selected by Rankin as commonly met with in men and three as more usually encountered in women. The conditions among the men are arteriosclerosis, interstitial nephritis, and diabetes; among the women—colitis, rheumatoid arthritis and hyperthyroidism. Illustrative cases are cited.

Bone Grafting in Ununited Fractures of Mandible.—This method of using a sliding bone graft taken from the jaw itself was described in The Journal, May 11, 1918, p. 1400.

*Wound Treatment by Living Cultures of Proteolytic Spore-Bearing Anaerobe Introduced into Wound. R. Donaldson.—p. 3.
Income Tax Information. J. Burns.—p. 35.

Wound Treatment with Bacteria Culture.—The fact that all successfully treated salt-bag wounds emitted a strong offensive odor, which was completely absent from other cases, led Donaldson to investigate the anaerobic bacteria present in wounds undergoing successful salt-pack treatment. The first case from which he made cultures yielded a mixture of two spore-bearing anaerobes which he ultimately succeeded in separating. One of these organisms possessed round terminal spores, the other oval subterminal ones. Pure cultures of the latter, grown for two or three days in cooked meat medium, developed the same peculiar odor which characterized successful salt-packed wounds. Further investigation of a series of cases so treated showed that this bacillus was present in all cases that were doing well and smelling, but that it was invariably absent from those cases which were making no progress. It established the fact that this particular odor might be regarded as an indicator of the success of the salt packs in any given case. Donaldson names the organism thus isolated, the "Reading bacillus." It is closely related to the *B. sporogenes* of Metchnikoff. Donaldson believes that this bacillus plays an important rôle in the healing of wounds because it disintegrates not only sloughs but also toxins of protein composition by means of an enzyme or enzymes which it produces. The enzyme is of the nature of a protease and can be demonstrated in filtrates obtained from broth cultures of the organism.

To prove the correctness of this theory a suitable gunshot wound was sowed liberally with a living culture of the bacillus, after which the wound was immediately repacked in the usual way. In three days time the patient's temperature had come down, the wound was emitting the characteristic foul odor associated with the active proliferation of the Reading bacillus and the patient was comfortable. The packing was left in situ untouched for some days, and within a day or two of its removal the wound was found to be absolutely clean, devoid of all sloughs, a brilliant scarlet color like fresh raw beef, and covered with healthly granulations. Since then, wounds of various kinds, such as septic knee joints, etc., have been sown, always with successful results and never with any ill effects. The advantages claimed for this method of wound treatment include: Simplicity of application, the avoidance of daily dressing and daily disturbance of the wound, the rapidity with which a sloughy wound becomes a healthy granulating surface, the absence of secondary hemorrhage, together with the remarkable and speedy improvement which takes place in the general condition of the patient, all of which mean considerable curtailment of the time generally spent by a wounded man in hospital.

*Quinin Administration. R. Howard.—p. 2.

Treatment of Malaria with Quinin Hydrochlorid.—For twenty years Howard has used the hydrochlorid and bihydrochlorid of quinin in the treatment of malaria. For routine prophylaxis he uses the hydrochlorid, either in tablet form or in solution, in which case he usually adds 1 minim of dilute hydrochloric acid to each grain of quinin to convert it into the bihydrochlorid. For the treatment of definite malarial pyrexia, he uses the bihydrochlorid. If a patient is very susceptible to quinin and complains much of tinnitus, this may sometimes be decreased by giving a few minims of dilute hydrobromic acid at the same time as the quinin. In the treatment of native infants with malaria, the tannate of quinin, given as a powder, in relatively large doses, has proved satisfactory.

*Molybdenotungsten Arc in Treatment of Suppurative Lesions. B. M. Young.—p. 108.
Plastic Vocal Cord. F. N. Smith.—p. 108.

Examination of Vermiform Appendix by Roentgen Rays.—An account is given of the methods and manipulations which have been found useful in the roentgen examination of 300 appendices. Details are given of thirty-six cases in which the roentgenologist's reports are compared with the operative findings. In all of these cases the diagnosis was verified at the operation.

Acute Appendicitis and Acute Appendicular Obstruction.—The results following 131 consecutive urgent operations for acute disease of the apendix are analyzed by Irwin. This list of cases includes operations performed in the most unpromising surgical surroundings, both in respect of the operation itself and of the subsequent nursing, though there seems to be often more risk in the removal of a patient in certain types of the disease than in operating where few facilities are at hand and many things must be improvised. Out of the 131 cases, eighty-four had already gone to suppuration. All excepting one, and that one already perforated, were operated on as soon as seen. There were eighty-nine cases of acute appendicular obstruction, of which ten showed obstruction only, eighteen showed obstruction with a varying amount of gangrene of the wall, and in fifty-nine rupture of the appendix had followed the gangrene. In the obstructive cases it is Irwin's contention that the primary cause of the disease is obstruction of the lumen of the appendix. On examination of the appendixes removed at operation it was found that obstruction may be due to one of five causes: (1) concretions (fifty cases); (2) strictures (six cases); (3) kinks (rare); (4) bands; (5) worms, fruit seeds, and other foreign bodies.

Control of Upper Fracture Fragment.—Lee describes a pelvic-femur splint and a thorax-arm splint which he has used successfully in cases of fracture of the femur and humerus.

Meningococcus Bronchopneumonia in Influenza.—In the postmortem examination of thirty-six men who had died from bronchopneumonia following influenza, gram-negative cocci were the predominant organisms found by Fletcher in the lungs of eleven cases. All the men, with one exception, had been taken ill on board the same transport. In six cases these gram-negative cocci were Type II meningococci and in one case they belonged to Type I. In four instances the cocci were not tested by agglutination. In each of the eleven cases Pfeiffer's bacillus was found in symbiosis with the gram-negative cocci. It is evident that the meningococcus, like other "respiratory" organisms, may, when it occurs in conjunction with Pfeiffer's bacillus, produce a fatal bronchopneumonia.

Apparent Immunity from Influenza at Public School.—Quarantine, the Ormeston nasal drill and the use of a prophylactic vaccine were the methods used by Friend.

Case of Pericardiotomy.—Pericardiotomy was performed by Noble and Vine on the twelfth day after passage of a rifle bullet through the chest, with recovery of the patient.

Molybdenotungsten Arc in Treatment of Suppurative Lesions.—The cases selected by Young for treatment were chiefly those which were of considerable duration and which showed little or no improvement obtained by previous methods of treatment. The exposure given was generally three minutes at a distance of 50 cm. from the arc. In practically all cases the dressings used were gauze damped with sterile water; in a few cases normal saline was used. This was adopted as it was desirable to eliminate any cause of improvement, or the reverse, other than the effects of the ultraviolet rays produced by this arc. In the acute lesions, frost-bite, carbuncles, large areas of inflamed and ulcerated skin responded readily. In thirty-eight cases of generalized sores many were healed more speedily by this method of treatmnt. Cases of bubo which had been incised were treated from the outset with daily exposures of three minutes, and each healed in eight days, leaving a narrow healthy linear scar, comparing favorably with cases treated in the usual way. The lamp employed is the "meridian" automatic feed arc fitted with the new molybdenotungsten electrodes. It is connected in the usual manner with the ordinary house supply, and is a suitable contrivance for all voltages above 100 volts, both direct and alternating current.

*Skin Reactions to Tuberculin, etc., G. Delamare.—p. 451.
*High Sugar Content of Spinal Fluid Outside of Diabetes. M. P. Weil.—p. 463.

Surgery for Diabetics.—Labbé declares that while it is advisable to refrain from operations on diabetics, especially when there is acidosis, yet it is better to operate than to let the patient die from septicemia or from the acidosis which it induces. When possible, the operation should be preceded by measures to reduce the hyperglycemia and the acidosis. This can be accomplished by a mixed diet with little meat and not much carbohydrates, if the patient does not exhibit acidosis. If there is acidosis, the diet must be restricted to dried vegetables or oatmeal or milk. Sodium bicarbonate should be given in sufficient amounts to render the urine alkaline. Another precaution is to refrain from imposing the usual fast just before the operation. It might be well besides to give 40 gm. of sodium bicarbonate before. The choice of the anesthetic is extremely important. Local anesthesia should be preferred; if this is not possible the next choice is spinal anesthesia. If a general anesthesia is necessary, ethyl chlorid should be the choice; chloroform or ether should never be used on a diabetic with acidosis. After the operation, enough sodium bicarbonate should be given to render the urine alkaline. It can be given by the mouth or by the vein. If there are evidences of severe acidosis, fully 100 gm. of sodium bicarbonate should be incorporated. As soon as nourishment can be taken, vegetable broth should be given or oatmeal gruel, soft mashed peas or beans or milk. The alkaline treatment should be continued until the acidosis has disappeared.

Tumors of Embryonic Type in Kidney Region.—Lutembacher comments on the strange succession of organs in the kidney region in the course of embryonal development, a succession of transformations which explain the frequency and the variety of tumors in this area. A case is described with twenty-five illustrations in which a woman of 36, exceptionally robust, suddenly developed severe dyspnea, the result of a left pneumothorax which spread to both lungs and proved fatal. The pneumothorax was the result of the bursting of numerous emphysema vesicles in the lungs, and there was also embolism of sarcomatous tissue. The cancerous emboli were traced to a number of renal tumors of embryonic type, each one suggesting that it was a lobe of the kidney which had been arrested in its growth. The spleen was also involved.

Skin Reactions.—Delamare has been studying the reaction induced by application of the skin tuberculin test, and also tests with plain horse serum, diphtheria antitoxin, and vaccines against typhoid and cholera. He was unable to detect any relation between the intensity of the reaction and the greater or less activity of the tuberculous process in the 300 tuberculous tested with the tuberculin skin test. The tendency to reactivation displayed by some old healed processes under the influence of the skin tuberculin test suggests that the cutaneous reaction is not altogether and simply a local process. Plain horse serum induced a reaction in the six tuberculous given the test. There were five positive reactions in ten tuberculous tested with diphtheria antitoxin, and in thirty-eight of thirty-nine tested with antityphoid vaccine and in ten of ten tested with anticholera vaccine. These reactions all differed essentially from the reaction to the skin tuberculin test.

Sugar in the Spinal Fluid.—Weil is inclined to attribute more importance to the sugar content of the cerebrospinal fluid than to any other element in it, as this reveals changes which otherwise might be overlooked. He says that the Bertrand technic for determination of the sugar content is reliable; applied to different specimens of the same individual fluid it gave him absolutely concordant results. It is based on the transformation of ferric sulphate into ferrous sulphate after it has been acted on by the precipitate of cuprous oxid resulting from reduction of the sugar by Fehling's reagent. The reoxidation of the ferrous sulphate into ferric sulphate is obtained with potassium permanganate. The technic is described in detail. In the spinal fluid from twenty-eight normal persons, the sugar content ranged from 0.42 to 0.60 gm. per liter. The normal average seems to be thus about 0.50 gm. When it is above this range, Weil calls the condition hyperglycorachy, and analyzes extensive experiences which indicate that this condition follows lesions or derangement of the peripheral motor or sensory neurons, in war neuroses, in shell shock, in epilepsy, etc. He theorizes to explain it as the result of congestion and of irritation of the sugar regulating ganglion in the floor of the fourth ventricle. With simple congestion of the meninges, the sugar content is increased, while it is decreased when there is bacterial activity. An increase therefore in the course of meningitis is a sign that the infectious process is becoming attenuated. In syphilitic meningitis the sugar content is generally increased. The sugar content of the spinal fluid may turn the scale in favor of an organic lesion when malingering is suspected.

Nervous Complications of Influenza in Children.—D'Espine reports two cases in which the children of about 6 presented symptoms referable to the brain and meninges during influenza. The diagnosis of meningo-encephalitis was confirmed by the numbers of polynuclear leukocytes in the cerebrospinal fluid anl also by two symptoms—somnolency and paresis of the cranial nerves arising in the mid-brain—which are the main symptoms on which the clinical conception of lethargic encephalitis is based. As the fever dropped, an abrupt turn for the better followed, the improvement amounting to an actual resurrection. The only treatment seems to have been lumbar puncture, once in one case and three in the other. General convulsions developed in the course of established influenza in two little girls, previously healthy and the children died within twenty-four hours. The incessant clonic contractions were like electric shocks, but the lumbar fluid showed no signs of meningitis, although under high pressure. The influenzal toxin had affected the nerve centers beyond repair.

Child Welfare Work in the United States.—Armand-Delille has been studying in this country the ways and means adopted to reduce infant mortality, and this is his report. He was escorted on his mission by Dr. W. P. Lucas, professor of pediatrics at the University of San Francisco and chief of the Children's Bureau of the American Red Cross. Delille remarks that the child welfare work at Cleveland seems to be the best organized and shows the most complete results. In conclusion he calls attention to the visiting nurse system, the federation of welfare agencies, and the children's bureaus as worthy of special emulation.

Xerophthalmia in Infant from One-Sided Diet.—The child, 27 months old, had been fed exclusively for the last fifteen months on vegetable soup (*bouillon de légumes*), the family physician warning that cow's milk would kill the child. The infant often had green diarrhea and was always apathetic and drowsy. Finally xerophthalmia developed on this *diète maigre,* but it retrogressed completely by the tenth day after the bowels had been cleared with calomel, and cow's milk gradually commenced. By the third day it was taking pure cow's milk by the tablespoonful and then cod liver oil was commenced. The child gradually recuperated.

Case of Macrodactylia. Laignel-Lavastine and M. Viard.—p. 1030.
*Experimental Typhoidal Fever. G. Blanc and J. Pignot.—p. 1035.

Purulent Pleurisy after Typhoid.—The special feature of this case was the association in a typhoid convalescent of the gas bacillus (*B. perfringens*) and the pyocyaneus in the purulent effusion following a hemorrhagic pleural effusion consecutive to an infarct in the lung, with final recovery.

Chronic Amebic Hepatitis.—Paisseau and Hutinel remark that acute hepatitis and abscess of the liver, the work of the ameba, are well known but a chronic form is not generally admitted. They have encountered a number of chronic cases however, developing in successive spurts but with no tendency to suppuration. The symptoms are those of subdiaphragmatic hepatitis. Pain in the right shoulder is more common than with abscess of the liver, and may keep up for months. There are also xiphoid and sternomastoid points on the phrenic nerve which are of differential value. In some of the cases the liver signs were slight and vague, the respiratory phenomena predominating. In some patients they extended to the other lung, and the diagnosis had been bronchitis or emphysema. The general condition keeps good, as a rule, but in some there was a tendency to progressive debility. In some cases the *poussées* of the disease had returned at intervals for six months or years or nine years in one case. The disease is eminently amenable to emetin but in the older cases prolonged treatment is necessary. To ward off danger from cumulative action, they inject 8 cg. per day for six days and then wait a month before resuming with 6 cg. for eight days, keeping on with the drug in alternate months, 4 cg., for ten days, repeating this three or four times.

The English Anti-Influenza Vaccine.—Rénon and Mignot report eight cases of grave influenza given this vaccine. Three of the men died. The effect of the vaccine was surpassed by that of antipneumococcus serum. The vaccine contains pneumococci, influenza bacilli and streptococci.

Aseptic Bloody Pleural Effusion in Influenza.—Richet and Barbier have had five cases of this kind. Between the fifth and the eighth days the signs indicate a pleural effusion but puncture brings nearly pure blood. This did not seem to modify the clinical picture unfavorably, four patients rapidly recovering. The fifth succumbed to his bronchopneumonia.

Disordered Heart Action.—Merklen has been sending soldiers with disordered heart action to a certain reeducation center where they were given three weeks of training, walks, fetching wood and water, etc. By the end of this time a good idea has been obtained of the true functional capacity of the heart.

Inorganic Murmurs in Young Recruits.—Aubertin found inorganic murmurs in from 20 to 30 per cent. of the class of 1920, and he is inclined to ascribe them to emotional causes, possibly demonstrating an instability of the heart action.

Symptoms from Injury of Frontal Lobe.—D'Oelsnitz reports a case of injury of the left frontal region with right hemiplegia and aphasia, and a transient change in character which he describes as *discordant euphoria*, the man growing more contented and smiling as his condition grew worse. Pupil changes were also observed but after evacuation of a pus pocket in the frontal lobe the character and pupils returned to normal.

Experimental Typhoidal Fever.—Blanc and Pignot injected some guinea-pigs in the peritoneum with 3 c.c. of blood from a typhoid case with fever of 105 F. The blood drawn from the arm was inoculated at once without defibrination. In two hours the guinea-pigs' temperature dropped lower than usual and then rose above normal, reaching 104 F. one day and keeping high for several days. This result was obtained in two of the three guinea-pigs, and suggests that with this technic experimental typhoid may be realized.

*Washing Out Meningeal Spaces. Bellin, Aloin and Vernet.—p. 455.
*Primary Treatment of Fractured Femur. R. Leriche.—p. 489.

Fractures of Lower Jaw.—Imbert and Réal have charge of a center for reconstruction of the face and jaws, and they have had twenty wax casts made of the main types of fracture of the lower jaw in their more than 1,000 cases. These casts have been deposited in the military museum at Paris, but they give photographs of them here with the type of prosthesis required for each. Some of the fractures are like those observed in peace.

Loose Joints After Resections.—Tavernier and Jalifier have operated for flail joints in 5 elbow cases, 3 shoulder, 2 wrists and one knee case. The results were so gratifying in most cases that they now propose intervention in merely loose joints, not restricting it to actual flail joints. In some of the joints, a wire holding the bones loosely together answered the purpose. In cases with a gap in the bone, an autograft, held in place with wire, gave a solid joint (wrist) with good functional results. With the knee, solid ankylosis is all that it is possible to attain.

Carrel's Treatment of Fistulas, etc.—Rendu's experience at a hospital in the rear with 200 cases shows that the Carrel method is for immediate application after the injury. Later than this, it may give good results in superficial injuries, but it cannot be trusted for deep bone and joint processes. It failed invariably in femur fracture cases, in osteitis, osteomyelitis and their fistulas. The Carrel tubes do not provide sufficiently for drainage. This must always be ensured at the lowest point possible. The skin must be protected with petrolatum, and hemostasis must be ensured beforehand, as the antiseptic fluid dissolves clots and may start bleeding anew.

Hemorrhage After Disarticulation of Shoulder.—Viannay refers to infected cases. By preventive ligation of the subclavian a few days after the operation, he was able to forestall the secondary hemorrhage which had proved fatal in some of his cases.

Recurring Dislocation of Shoulder.—The dislocation had recurred nine times during the year, but no cause could be discovered except that the shoulder was a little loose. This was corrected by taking up folds in the abnormally large and loose capsule of the joint with interrupted sutures, passing the threads through the subscapular muscle. The intervention was a complete success; the young man was soon drilling with the other recruits.

Arthrotomy of the Knee.—Badolle emphasizes that at every operation on the knee the ultimate orthopedic result should always guide the surgeon. Only a typical resection at first ensures a solid, usable knee.

Tardy Arthrotomy with Primary Suture.—Trillat reports four cases in which an interval of from twenty-seven to thirty-one hours had elapsed after the injury before the operation on the knee. He sutured at once, although infection seemed to be installed, and healing occurred by primary intention in each case.

Regeneration of Bone.—In Duhamel's case a gap of 5 cm. in the shaft of the humerus became regenerated within two months, without any shortening of the arm. The fresh periosteum (ten hours) lined with particles of bone left from the sequestrectomy, shaved off with Ollier's sharp bone-scraper, and sheltered by the primary suture against mechanical, chemical or inflammatory irritations, was able to reconstruct this large shaft in this short period. He scrapes the sequester with a sharp rasp, the sequester held with forceps, and lines the periosteum with these scraps of bone. Lamare's success was equally good after a similar subperiosteal sequestrectomy. The gap was 2 to 5 cm. long in the tibia. Consolidation was complete in eight months.

Washing Out the Meningeal Cavities.—Bellin and his co-workers recall that diffuse meningitis originating in the ear—streptococcus meningitis—is often fatal, and heroic measures are justified. In a case described, osteitis of the tip of the petrous bone led to generalized meningitis. They punctured the lateral ventricle, after lumbar puncture, and then injected saline or antistreptococcus serum, tinted with methylene blue, into the lumbar trocar. The fluid emerged in the ventricle, thus rinsing out the meningeal cavity on its way. This is the fourth case on record of this lavage of the meningeal cavities, and the immediate benefit was most striking. The improvement lasted only a few days, and repetition of the lavage proved ineffectual, as the osteitis at this point had escaped discovery and had continued its course. Of the four cases on record, one may be considered a success. In the others, conditions outside of the meninges precluded recovery.

Experiments on the cadaver have confirmed the simplicity and feasibility of this rinsing out the meningeal cavities. General anesthesia is not necessary. From 100 to 400 gm. of fluid can thus be sent through from the lumbar puncture needle to the ventricular puncture needle, or vice versa, repeated as needed. A mechanical and a biologic effect can be realized simultaneously by combining saline with the special antiserum or some weak antiseptic. The procedure is not dangerous, they say, if the fluid is injected slowly, without pressure. In their case, slight transient dyspnea was the only by-effect. It probably corresponded to the passage of the fluid past the medulla oblongata. The benefit from the lavage amounted, they add, to an actual resurrection for four days. The one successful case was a meningitis after trephining. The micrococcus involved was the *M. pharyngis cinereus.* They punctured the ventricle through a small trephining opening, 3 cm. above the meatus of the ear, introducing the needle perpendicular to the external surface of the brain, to a depth of 3 cm., on a level with the temporal cornu (second temporal circonvolution).

Fracture of the Femur.—Leriche declares that it is the lesions of the soft parts, rather than of the bone, that render the prognosis grave, and treatment should be guided by this fact, as he describes in detail.

*False Appendicitis in Influenza. E. Villard.—p. 534.
Combined Wheeled Stretcher and Table. J. Molinié.—p. 543.
Malaria in Morocco. L. Langeron.—p. 547.

False Appendicitis in Influenza.—Villard has encountered several cases that presented the clinical picture of acute appendicitis and an operation seemed urgent at first. Study of the cases, however, showed that general symptoms, chill, malaise and feeling of distress had occurred hours before any local symptoms had developed. The local pain, besides, was more epigastric than appendicular, and it was paroxysmal instead of constant. The temperature curve resembles that with pneumonia and the pulse keeps relatively slow, in marked contrast to the high fever. The patients affected had all been in contact with influenza cases and the onset was typical of grippe. The abdomen is distended and palpation is painful throughout, most marked in the right iliac fossa. Vomiting follows and symptoms of intestinal obstruction. Respiration is regular and the tongue does not look like the appendicitis tongue. In twenty-four hours the symptomatic picture is complete. In all his cases the symptoms gradually subsided under treatment. The persistence of the asthenia and fever and the development later of pulmonary disturbances of the bronchopneumonic form confirmed the diagnosis of influenza. An operation is not only needless, but liable to be dangerous from the depressing effect of the anesthetic and its influence on the air passages. Enemas of boiled water with or without glycerin or oil and ice to the abdomen are about all that is needed.

*Treatment of Scoliosis. Joland.—p. 25.

Dyspepsia in Infants from Cow's Milk.—Marfan emphasizes the necessity for being on the alert to detect digestive disturbances which sometimes occur when cow's milk is substituted for breast milk. These disturbances often prove the first link in the chain which leads to athrepsia. The principal symptom is the putty stool. These stools may be normal in number but they look like soft putty or clay, and they scarcely soil the diaper. Scraps of mucus on the surface, the larger bulk, the strongly alkaline reaction, and the ammoniacal and putrid odor are special features. There is no diarrhea but there may be a tendency to constipation. The stools show an excess of alkaline-earthy soaps and of minerals, evidences of incomplete digestion of casein, and the bile pigments are present in the form of urobilinogen.

The outcome is generally favorable for infants over 6 months old, but younger than this, if breast milk and hygienic conditions are not available, especially if there is an inherited taint, the prognosis is almost inevitably fatal. Dropping the cow's milk in time puts an end to this dyspepsia from cow's milk, and sometimes all disturbances cease when the milk is diluted further.

Even when an infant is apparently thriving on cow's milk, the character of its stools, the multiple bacterial flora and high mineral content, show that the state of health is very close to the borderline of disease. The defective utilization of fat is shown by the insoluble calcium and magnesium soaps in the stools, the fat in them being thus lost for nutrition. There may also be some intoxication from absorption of the products of putrefaction. In treatment, if breast milk is not available, asses' milk is the next choice, and failing this, modified milk, such as buttermilk, condensed or sweetened skimmed milk. The digestive apparatus must be given a chance to rest, beginning with small amounts even of breast milk. The casein in cow's milk must be rendered easier of digestion, by cooking or enzyme action. The fat in the milk should be reduced, and some easily digested carbohydrate should be added. He gives minute directions for the diet under 4 or 6 months and above this age, warning against the tendency to give too much starchy foods to older infants. Otherwise starch dyspepsia follows on the cow's milk dyspepsia.

Antituberculosis Dispensary for Children.—Guinon insists that the preventorium should be for the entire family, not adults alone or children.

Digestive Disturbances in Infants.—Terrien warns that the new conceptions in regard to dyspepsia in infants are new only in name. An infant who is digesting defectively a certain ration of milk, digests it still more defectively when the amounts given are increased. This is a natural consequence that everyone knows, but Finkelstein has written reams about it as the "paradoxic reaction." The famous "albumin milk" is not keeping its promise; to feed casein and no carbohydrate is not tolerated by the organism, and Finkelstein and Combe soon advised addition of maltose, 30 gm. to the liter, while Combe adds up to 8 per cent. Thus modified, the "albumin milk" is practically the old familiar mixture of malt extract and curds (*bouillie de malt et lait caillé*).

Tabes in Children.—Lereboullet and Mouzon report a case of tabes from inherited syphilis in a boy of 15, who has been under observation for two years. The symptoms were not very pronounced but they were unmistakable. They began with right ocular paralysis and ptosis, and a violent cramp in the right leg lasting all day. The Argyll Robertson sign, the abnormal reflexes, and lymphocytosis in the spinal fluid confirmed the diagnosis. Under treatment the symptoms subsided except for the rigidity of the pupils and the loss of the tendon reflexes on both sides. The Wassermann reaction was positive as also in the lad's mother and younger brother. Two similar cases are mentioned further, the ocular paralysis and abolition of the tendon reflexes being accompanied by a positive seroreaction. The favorable modification under specific treatment confirms the diagnosis, and suggests that possibly tabes in adults may in certain cases be due to inherited syphilis. More careful examination of children might reveal this tendency to tabes in time to ward off serious trouble later. The alarm should be sounded with persisting migraine, tendency to spasmophilia, nocturnal incontinence of urine, simple transient "absences" as manifestations of abortive epileptiform seizures, inability to keep up with his class in school, tics, a little choreic instability, disturbance in vision, or cramps in one limb. In their patient there was no disturbance in gait, even with the eyes closed.

Gymnastic Exercises in Treatment of Scoliosis.—Joland reaffirms the advantages of the proper gymnastic exercises in treatment of scoliosis as the only means to reestablish the normal balance of the spine, suppressing the causes of asymmetry and combating the cause of the deformity. They should be kept up at home for years. The shape of the bone is secondary to the function. Nageotte has reported the case of a girl with one leg left 4 cm. shorter than the other after an accident. The scoliosis induced to keep from falling resulted in modifying the shape of certain vertebrae to correspond.

*Lethargic Encephalitis. Chartier.—p. 660.
General Anesthesia and the Circulatory Apparatus. L. Binet.—p. 661.

Arteriovenous Aneurysms.—Chevrier reviews his extensive experience with the clinical and the anatomic transformations of arteriovenous aneurysms. In two of his cases the arteriovenous aneurysm became transformed into an arterial form, and this retrogressed spontaneously and totally in one case, partially in the other. The clinical and the anatomic transformation do not always apparently coincide.

Edema of Hand and Arm.—Sollier and Courbon have recently encountered four cases in which a seton bullet wound in the back of the neck was followed by edema of the hand and fingers, with mydriasis suggesting pressure on the sympathetic nerve. The nerve could not have been directly injured by the projectile.

Grafts of Dead Nerve Tissue.—Sencert discusses the preferable technic for bridging gaps in nerves in a way to permit regeneration, and describes favorable results in his fifteen operations of the kind with the *hétérogreffe morte*. His first operation was done in March, 1918, and the interval since has been too short for decisive judgment as to the functional outcome. But in two of the cases there is a beginning of functional restoration which is most encouraging, and in one other case an operation, less than three months later, revealed that the continuity of the nerve has been completely reestablished with no cicatricial tissue production. Illustrations of this case are given. The sciatic nerve from a calf was inserted to bridge a gap of 2 cm. in the median nerve. The bundles of nerve fibers are approximated and sutured separately, a "fascicular graft." The technic is described in detail.

Paradoxic Electric Contraction.—Palmes and Hanns noted this paradoxic contraction by unipolar tetanization in cases of injury of peripheral nerves, central lesions and reflex disturbances, but never in purely psychic motor disturbance.

Lethargic Encephalitis.—Chartier insists that all other forms of encephalitis should be distinguished from this "lethargic" type, before we can accept it as a new entity. He recalls further that Leichtenstein and Strümpell in 1892, called attention to the frequent grippal origin of acute hemorrhagic encephalitis. F. Raymond also has emphasized "that in epidemics of influenza some cases are encountered in which from the very first the patients present symptoms of acute encephalitis with the signs of grippal infection."

Treatment of War Wounds. L. C. Bailleul and G. Worms.—p. 428.

Intravenous Injections of Camphorated Oil in Influenza.—Loeper and Fumouze refer to the form of influenza characterized by asphyxia, a vaso-paralytic or vago-paralytic form. In the last two months this grave form amounted to 10 per cent. of their total cases. With venesection, abundant and repeated, followed by subcutaneous or intramuscular injection of sugar or epinephrin in physiologic solutions, and daily intravenous injection of 2 c.c. of 10 per cent. camphorated oil, from 55 to 60 per cent. of their thirty-eight patients in this grave group recovered.

Hexamethylenamin by the Vein in Pleurisy.—Loeper and Grosdidier report that they have applied this treatment in thirty-two cases of pleurisy, and recovery followed in from seven to twenty-five days with from five to ten or twelve injections. They say that it seems to promote the diuresis and the resolution of the effusion, while the accelerated elimination of toxic products aids in reducing the fever.

*Vicious Circle After Gastro-Enterostomy. H. Vulliet.—p. 673.
Digitalis Preparation Effectual by Rectum. J. Morin.—p. 694.
*Malignant Influenza. G. A. Krafft.—p. 703.

The Vicious Circle After Gastro-Enterostomy.—Vulliet reports eight cases with illustrations to show the various mishaps liable with posterior gastro-enterostomy. In three out of four of the cases a secondary (anterior) gastro-enterostomy restored clinically normal conditions. Mobilization of the left portion of the duodenum is susceptible of rendering real service in gastro-intestinal surgery. In case of the vicious circle, it renders entero-anastomosis possible and this puts an end to the vicious circle. In fact, without it, entero-anastomosis is scarcely possible, after a correct posterior retrocolic enterostomy. It is a simple matter on the cadaver but may be difficult and risky in the living body. By left mobilization he means severing the duodenum at the pylorus. This releases the afferent loop of the duodenum in the gastro-enterostomy, and this pylorus end is swung around and sutured to the left aspect of the efferent loop.

A new anterior gastro-enterostomy is simple, easy and rapid and answers the desired purpose, breaking up the vicious circle equally as effectually. In some of the cases he describes, the stomach did not function well and evacuation was sluggish by any route. His one failure was in a psychopath with localization in the stomach. Only transient benefit was realized, and the woman of 45 died in a gradual decline three years later. Vulliet exclaims on the lack of any certain means of distinguishing between such cases and those in which a stomach lesion escapes our means of investigation and yet could be repaired by an operation.

Malignant Influenza in Swiss Troop.—Krafft says that 6 per cent. died of the 500 men in a Swiss troop stationed at a remote gun range, all but 20 of whom had contracted influenza. The influenza was often of a malignant type, with intense cyanosis. The measures which proved most effectual were venesection plus transfusion, and, at the beginning, 0.15 neo-arsphenamin. This had no action when the disease was at its height, but towards the close it displayed a very useful action again. Opium was proscribed throughout, and no food was given to tax the digestion while the influenza lasted, but sugar solution was injected freely.

*Severe Chronic Diarrhea. M. Düring.—p. 1697.
Traumatic Luxation of Ulnar Nerve. J. Dubs.—p. 1711.
*Transfusion of Blood after Abdominal Gunshot Wound. A. Fonio.—p. 1719.

Severe Chronic Diarrhea.—Düring describes cases, in a girl of 10 and three adults, which in many points resemble the severe alimentary diarrhea of infants. One man of 44, a prisoner of war in Germany, developed severe chronic diarrhea with great depression, but no pains or fever. No benefit was derived from tannin or opium preparations or charcoal. A bleeding bunch in the rectum was assumed to be cancer and the man was sent to Switzerland to be interned, where the rectal lesion subsided under silver nitrate. In all the cases in this group there was a history from youth of substandard digestive functioning, and the patients showed a tendency to anemia, meteorism in the upper abdomen, and a gray tint of the skin. The stools in each case showed defective digestion of carbohydrates, the high acidity testifying to abnormal fermentation, which was responsible for the meteorism and the excessive peristalsis. The correctness of this assumption was demonstrated in each case by the benefit from dietetic restrictions, avoiding carbohydrates. Any meal of potatoes or tapioca was liable to bring back the diarrhea. Carbohydrates have to be banished as completely as from the diet of diabetics. Further all cellulose-containing foods have to be scrupulously avoided. Lean meat, fish, eggs, cheese and cane sugar have to be the sole reliance. Coffee and tea with cream can be allowed, but no milk on account of its lactic acid content. Kefir is very useful. It is better to warm it. In the very severe cases, albumin milk may have to be resorted to.

He begins treatment with a purge, allowing only black tea, and for two or three days only fluid food. He warns expressly against gruels. The fluid stools soon stop, and meat and eggs soon bring putrefaction bacteria to predominate. In a few days the stools become formed and alkaline. In obstinate cases, calcium chlorid may hasten this transformation of the reaction. The amounts of the foods allowed can be rapidly increased and after a few weeks, zwieback and flour dishes may be cautiously allowed under constant supervision. Noodles, grits and rice may be taken without harm in time, but the intolerance for potato long persists, and it may bring on the gravest relapses. Institutional treatment is almost indispensable, even more so than for the graver cases of diabetes. Medicinal treatment is of little use except that opium may aid at first in checking the exaggerated peristalsis. With ulcerative colitis it can be given with belladonna by the rectum. Morphin may be useful to quiet the excited patient. After recovery, the patients long have to beware of foods containing cellulose. A limit of tolerance is finally reached, and keeping within this they have no further trouble. His patients in this group have been free from all disturbances for months.

Transfusion of Blood After Abdominal Injury.—Fonio reports the case of a young hunter who took up his gun by the muzzle and shot himself in the ileocecal region. The laparotomy three hours later showed fourteen perforations of the small intestine. The 95 cm. segment of intestine with twelve perforations and two holes in the mesentery was resected, and the two other perforations were sutured. The abdomen was flushed with saline until it came away clear. After the operation, 500 c.c. of saline with 7 drops of epinephrin were infused, the legs wound and raised, and tetanus serum, camphor, etc., injected. Six hours later, the radial pulse having become imperceptible, 250 c.c. blood from the patient's sister were transfused, and by the eighth day the young man was ready to return to work. He would undoubtedly have succumbed if it had not been for the transfusion of blood. The transfusion was done by the citrated method. The 250 c.c. blood sufficed to restore the pulse permanently. Fonio explains this benefit as due to the breaking up of the vicious circle by the influx of fresh blood supplying the heart muscle with blood through the coronary circulation, and thus giving it the nourishment needed to enable it to resume its task. This in turn supplied all the organs with nourishment and started normal functioning anew throughout the organism. He advises continuing the transfusion until the pulse is full and strong again. This occurred with 250 c.c. in his case. The patient vomited afterward, and albumin and casts appeared in the urine. Healthy, robust donors closely related to the patient, transfusion of not over 250 c.c., and waiting to note the effect of this, will ward off injurious by-effects. In urgent cases even the general practitioner need not hesitate to apply it; to facilitate this, he gives illustrations of the details of the technic. He ascribes the priority to Agote.

*Slight Chronic Fever Traced to Pharynx. U. Baccarani.—p. 749.

Chronic Fever of Pharyngeal Origin.—In the three cases described, a slight fever keeping up for months was finally traced, by exclusion, to chronic inflammation in the pharynx not severe enough to have attracted the patient's attention. In the three cases reported the appendix was tender and appendicectomy had been advised but the subsidence of the fever under treatment of the throat alone demonstrated that the appendix was not the main factor. The general health and the appetite kept good and there was nothing to suggest tuberculosis otherwise. No special germs could be cultivated from the throat.

Different Icterohemorrhagic Spirochetoses. G. Molinari.—p. 978.
*Right of Injured Workmen and Soldiers to Refuse Operation. E. Aievoli.—p. 980.

Nose and Throat Secretion in Influenza.—Musu and Russo state that in seventy-one cases of influenza in soldiers, sailors and civilians, the germ isolated recently by Scalone was found in the tonsils or nasopharynx in sixty. It was in pure culture in fifty-five. He calls it the *Micrococcus metatetragenus.* In eleven cases only streptococci and staphylococci could be cultivated.

Right of Injured Soldiers and Workmen to Refuse an Operation.—Aievoli refers to treatment predominantly surgical which would presumably restore greater earning power. He discusses the views advanced by competent authorities in Italy, France and elsewhere. The only solution, he says, seems to be an uplift of the psychologic reasoning of the classes involved. He warns, however, in conclusion against allowing correcting surgery and orthopedic treatment to be in the hands of any but the most competent, who have long given evidence of a "strict surgical conscience."

*The Retrococcygeal Diverticulum. D. V. Juaristi.—p. 311.
*Stenosis of Urethra. S. Pascual.—p. 322.

Architecture of the Pelvis.—Serés' long article has fifty-three illustrations showing the various stages of development of the pelvis and the soft parts and spaces, and pointing to more effectual routes for drainage, etc.

Retrococcygeal Diverticulum.—Juaristi has encountered a number of curious malformations resulting from the persistence of embryonal disposition of the terminal spinal cord. In some cases there was a depression or invagination of the skin over the coccyx, sometimes entailing a fistula; in other cases causing neuralgia, paralysis, or enuresis from dragging on the lower nerve roots. The diagnosis is simple and excision promptly cures the disturbances. Twelve illustrations show the different types.

Stenosis of the Urethra.—Pascual warns that retention should be ascertained by palpation of the bladder, not by introducing the catheter as the first step. And when the catheter is introduced, it should be a Guyon explorer, not the evacuating catheter. The stenosis thus ascertained, sitz or general hot baths, belladonna rectal suppositories, hot enemas and cataplasms with laudanum, in the hypogastric region, may induce micturition. If not, and if the stenosis is impassible, then the bladder must be punctured, which, he declares, is an absolutely harmless procedure and can be repeated many times. After the congestion has subsided, the stenosis may allow the passage of the catheter. If not, surgical measures are necessary as he describes in detail.

*Adiposis Dolorosa. J. Cecikas.—p. 1.
*Effectual Treatment of Malaria. J. P. Cardamatis.—p. 5.
Rheumatismal Origin of Certain Heart Symptoms. Parturier and Maroulis.—p. 18.

Cure of Adiposis Dolorosa.—Cecikas reports a case in a man of 32, married for six months, which, he thinks, throws light on the etiology of the disease. The pressure of the man's body against his desk explained the unusual location of the lipomas, and the immediate effect of an injection of pituitary extract on retention of urine confirmed the influence of the pituitary on the innervation of the bladder, but the primal factor in Dercum's disease seems to be some abnormal or lacking hormone from the organs of reproduction. This seems to upset the normal balance in the chromaffine system. His patient was clinically cured, even to the retrogression of the lipomas, by systematic treatment with extract of thyroid 1 part; extract of pituitary, 1 part, and of ovary 2 parts, supplemented by a vegetable diet and exercise in the country. Whenever this treatment was interrupted, the whole set of symptoms returned, even including some of the tumors. The patient learned to make his organotherapeutic products himself, making a cold extract of thyroid and testicles, 1:4, from sheep 1 or 2 years old. (Extraction cold; 50 c.c.; phenol, 0.05.) He took a teaspoonful of this extract morning and evening in warm soup. Cecikas recalls that Dercum in describing his first case of adiposis dolorosa noted its connection with the thyroid.

Effectual Treatment of Malaria.—Cardamatis insists that to give quinin in an ineffectual manner not only perpetuates malaria but drives the public to quacks. He has worked out a technic which has radically cured 98 per cent. of all types of malaria, and his experience and experimental research on the human have absolutely confirmed its efficacy, he reiterates. He has been in charge for many years of the state campaigns against endemic malaria at different points in Greece, and also of the campaigns under the auspices of the Hellenic Antimalaria League. Tens of thousands of malaria subjects have passed through his hands and been followed long enough for the ultimate outcome to be known. He declares that administration of quinin by the *mouth* is as effectual as by injection. His technic was worked out by comparative study of the effects on different series of six or eight groups of up to sixty persons each, with subgroups of eighteen with one of the three types of hematozoa in the blood, and two with mixed infection. The results in each series are grouped in a table for comparison. The effectual method proved to be as follows: He begins the course with 1.60 gm. at the first *moment* of defervescence, during the sweating stage. This dose is divided in two parts, taken at a half hour interval. After this, for eleven days, 1.50 gm. is given, seven or eight hours before the attack. Then suspension for four days, after which 1 gm. is taken each evening, not long before retiring, and this is repeated for eight consecutive days. Then suspension for a week, after which 1 gm. is taken at bedtime the sixth and seventh days of each week. This procedure was rigorously followed for two months in the case of vivax infection, benign tertian, and for three months with praecox or mixed tertian. After this, if the mosquito season is on, he advises preventive treatment, namely, the first and the second days 0.35 gm. and the third day 0.50 or 0.60 gm.

This whole procedure applied systematically and rigorously for several years has given results, he says, *littéralement miraculeux*, far superior to anything else known to date. That is, the radical cures have amounted to 98 per cent. By giving the quinin exactly from eight to seven hours before the attack, the largest quantity is absorbed just as the schizogony of the hematozoa reaches its highest point. Above the age of 17 the dosage is the same as for adults. For young infants he gives one eighth of the doses; from 1 to 2 years of age, one fourth; from 4 to 5, three eighths; from 6 to 9, one half; from 10 to 13, five eighths, and from 14 to 16, six eighths. In the exceptionally resistant cases he doubled the standard doses or took other exceptional means of quininization. Persons inoculated with infected anopheles and then given 0.40 gm. of quinin every day with 0.60 every third day, during the entire summer, never developed any symptoms of malaria. On the other hand, the same mosquitoes biting ten other persons who took afterward 1 gm. quinin for seven days, gave rise to malaria in 33 per cent. of the subjects, the ague developing in two or three weeks, with the praecox in the blood. The quinin used was the 0.2 gm. tablets supplied by the state.

*Case of Cesarean Section. H. S. Bholaraksha.—p. 66.
Sporadic Cases of Diphtheria at Bangkok. L. Robert.—p. 71.
*Alternating Amebic Appendicitis and Hepatitis. L. Robert and H. Sakda.—p. 79.

Cesarean Section.—The case described is the first known instance of cesarean section on a living woman performed in Siam.

Amebic Hepatitis and Appendicitis.—Robert and Sakda report the case of a medical army officer who developed dysentery apparently cured by emetin. Three years later, symptoms of appendicitis developed, but soon subsided as symptoms of hepatitis became manifest. Puncture of the liver showed amebas and colon bacilli in the pus. Amebas were then found in the stools. As the hepatitis subsided after clearing out the pus pocket, the appendicitis flared up again, and amebas and colon bacilli were found in the appendicitic pus. After this was cleared out complete clinical recovery followed. The ameba alone does not seem able to set up appendicitis, but it prepares the soil for the colon bacillus to start suppuration. The characteristic *balancement* between the liver and the intestinal lesions was marked in this case.

*Congenital Pigmentation of Cornea. P. J. Waardenburg.—p. 1741.
*Urticaria and Thyroid Functioning. H. Bolten.—p. 1747.

Congenital Pigmentation of the Cornea.—Waardenburg reports several cases of melanosis of the cornea. He is inclined to regard the pigmentation as merely a displacement of pigment, not an actual melanosis. No instance is known of cancer developing in an eye thus affected. He saw no evidences of a familial or hereditary character of the anomaly, and it did not seem to interfere with vision. The symmetrical pigmentation in one or both eyes was in the form of dark brown stripes, horizontal or vertical, or a stippled area. The iris was grey or brown.

Urticaria as Sign of Thyroid Deficiency.—Bolten describes four cases which apparently sustain his assumption that urticaria in some cases is due to thyroid insufficiency, inducing hypotony of the vegetative nervous system. One woman of 28 with signs of defective thyroid functioning developed transient urticaria after much muscular exertion, and also after emotional stress and during menstruation. In a girl of 19 similar trophic vasomotor phenomena were accompanied by symptoms of beginning epilepsy. After a brief course of thyroid treatment, there seemed to be no further tendency to urticaria. A woman of 30 had had slight exophthalmic goiter eight years before, and since then had developed transient urticaria whenever she was much fatigued or jealous. It used to last several days, but now she takes a tablet of thyroid extract when the urticaria appears, and it subsides at once. In a fourth case the symptoms indicate a high degree of vagotony. After fatigue or emotional stress, urticaria develops and sometimes a fleeting edema of the lips and eyelids.

He thinks that the term vagotony is too restricted; the irritability and weakness involve the whole of the sympathetic system, not the vagus alone. Urticaria sometimes accompanies various chronic conditions such as blood and liver disease, diabetes, tuberculosis, etc., in which the vegetative nervous system and the thyroid evidently have been damaged by the chronic ailment. For these and other reasons cited, he reiterates that urticaria is presumably a manifestation of hypotony of the vegetative nervous system, either congenital or the result of acquired thyroid insufficiency. The urticaria following the use of certain drugs, foods, etc., is explained by the same mechanism. The benefit from thyroid treatment is the most convincing support of this assumption in regard to urticaria—cutaneous asthma.

Conservative Treatment of Surgical Tuberculosis.—Hertz is in charge of a sea coast sanatorium for children in Denmark, and for the last five years he has been giving heliotherapy a very prominent place in the treatment of tuberculous processes in bones and joints. The sun baths are given for about six hours a day as the children recline or play or stroll about, unclothed, in the open air. For stormy weather there is a large hall like a greenhouse. In winter it can be warmed. The healthier children also play about or recline in their living rooms for several hours, unclothed, before the open windows. The reflection from the water of the bay enhances the effect of the sunlight. The children seem to bear low temperatures better when they are well tanned. At the Grimmenstein sanatorium near by, children of 4 years old and over bear it perfectly to lie unclothed in the open air at a temperatur of 6 Réamur (45½ F.) As there is so much strong wind at the sanatorium in his charge, he has a partial shelter for the children. He uses a quartz lamp for the weaklier children and has had good experiences with it. Rollier has reported from Leysin 79.3 per cent. cured of his spondylitis cases; 4.1 per cent. died. Hertz, with heliotherapy on the Danish sea coast, very nearly equalled this, with his 75 per cent. cured of 271 cases; 90 per cent. cured in 139 cases of coxitis; 97 per cent. cured of 74 cases of gonitis; 97 per cent. cured of 29 cases of spina ventosa; 92 per cent. in 50 cases of ostitis; 94 per cent. of 61 cases of mesenteric tuberculosis; 95 per cent. of 248 cases of adenitis, and 73 per cent. of the 11 cases of multiple bone and joint lesions. The cure has been permanent in a much larger number of cases, he asserts, than with the best surgical statistics, confirming Calot's dictum on surgical tuberculosis, *"Le bistouri, c'est l'ennemi."*

STAPHYLOCOCCUS AUREUS PNEUMONIA

H. T. CHICKERING, M.D. (NEW YORK)
Captain, M. C., U. S. Army
AND
JAMES H. PARK, JR., M.D. (HOUSTON, TEXAS)
First Lieutenant, M. C., U. S. Army
CAMP JACKSON, COLUMBIA, S. C.

In the standard textbooks the staphylococcus is usually noted among other micro-organisms as a possible etiologic agent in the production of bronchopneumonia. A detailed description of the clinical picture of the disease associated with the presence of this organism in the lung has thus far failed to come to our attention. This is no doubt due in part to the relative rarity of this infection as encountered in civil practice, and possibly to the lack of careful study of the bacteriology of acute respiratory affections until but recently. How rarely *Staphylococcus aureus* infection of the lung occurs and how grave the prognosis is may best be stated by noting that in a series of about 800 cases of pneumonia, drawn from all classes of the population of New York City, only thirteen cases were treated at the hospital of the Rockefeller Institute under the direction of Dr. Rufus Cole, in a period of five years from 1913 to 1918, and of these, ten patients died. Some of these cases of bronchopneumonia were apparently secondary to local infections elsewhere in the body. Two seemed to be due to a primary infection of a finger and the scalp. One followed a severe attack of measles; another complicated a Type IV pneumococcus pneumonia. In most instances, however, it was impossible to find any antecedent infection, and the lungs appeared to be involved primarily.

During the present epidemic of influenza at Camp Jackson, S. C., which began about September 15 and continued for practically one month, a very unusual opportunity was afforded to study this infection in the medical clinic, under the direction of Major W. W. Herrick, chief of the medical service. In this period about 8,100 patients, chiefly soldiers, were admitted to the base hospital with an acute febrile condition accompanied by inflammatory changes of the upper respiratory passages and diagnosed influenza. The majority of these men after from three to five days of fever made a rapid and uneventful convalescence, returning to duty within a week or ten days. On the other hand, approximately 1,400 either continued to have fever and prostration, or after an afebrile period of from three to seven days began to show clinical evidence of inflammatory change in the deeper air passages of the lungs, and the condition was diagnosed as *pneumonia*, either broncho or lobar in type. Many of these cases of pneumonia were relatively mild, only parts of one or two lobes being involved, usually the lower lobes and the dependent portions.

The examination of the sputum of these patients showed most frequently the presence of the pneumococcus, especially the strains designated as Type IV, less often *B. influenzae*, various types of streptococci, and various members of the gram-negative diplococcus group, usually *M. catarrhalis* or *M. flavus*. A certain number of cases, relatively few as compared with the total number of cases of pneumonia, but large when correlated with the total number of deaths, presented an entirely different picture. These patients were extremely prostrated almost from the onset of their infection. After being ill from three to four days with influenza, their condition became critical. They exhibited an unusual type of cyanosis. The cherry-red indigo-blue color was indeed very striking, though not pathognomonic of the infection to be described more fully, that associated with *Staphylococcus aureus*.

CLINICAL FEATURES OF THE DISEASE

The onset of *Staphylococcus aureus* pneumonia is almost always insidious and rarely accompanied by the chill and localized pain of a typical lobar pneumonia, though the course of the disease is extremely rapid. The facies, the anxious expression, and deep cyanosis suggest a grave prognosis from the onset, at a period when physical signs of pulmonary involvement are but scanty. Herpetic eruptions on the lips are scarcely ever noted, nor is delirium present except rarely. Usually the mind is clear almost to the end. Epistaxis is not uncommon. Occasionally pleuritic pain is complained of, but this is not usual. It is the picture of a general septicemia, so often seen in puerperal sepsis when the patient so little realizes the close proximity of death. Sweating is not a striking symptom of this type of infection, though near the end, the skin frequently becomes moist and later clammy. The fever on the whole is high, ranging between 104 and 106, with frequent remissions to 101. The pulse is relatively slow, at the onset under 100, and in only a few cases does it rise above 120 until just before death. The quality of the pulse, on the other hand, is usually poor, small, weak, and in many cases almost imperceptible. Respirations usually range between 24 and 36 and in some cases rise to 50 or 60 without much obvious discomfort. These patients rarely have the painful and labored breathing seen in pneumococcus infections.

Figure 1 illustrates the typical course of the disease in a patient who developed his infection in the hospital:

A white soldier, aged 22, and a native of Alabama, was admitted to the hospital, *Sept. 6, 1918*, about a week before the first cases of influenza began to appear in camp. He had

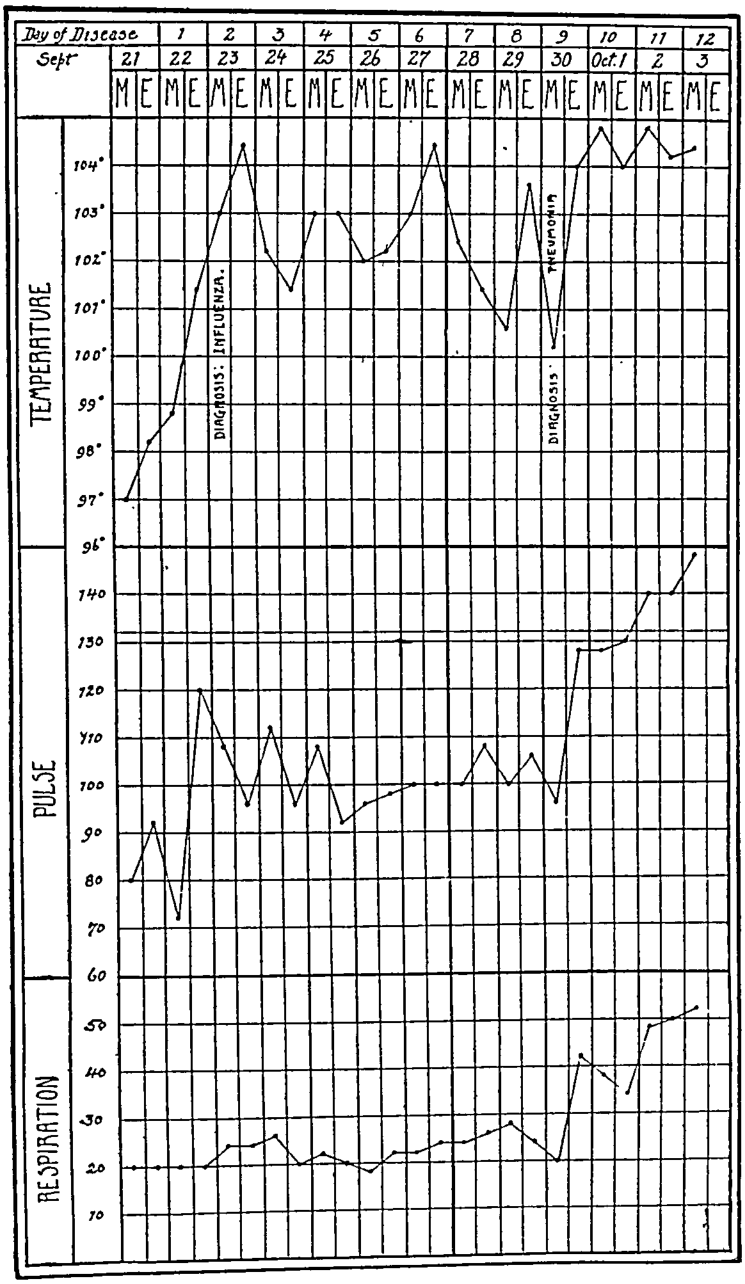

Fig. 1.—Temperature, pulse and respiration chart in a case of influenza and of bronchopneumonia of the right and left lower lobes that developed in a farmer from Alabama admitted to the hospital because of estivo-autumnal malaria. Blood count, October 3: white blood cells, 5,100; polymorphonuclears, 86 per cent.; lymphocytes, 13 per cent.; large mononuclears, 1 per cent.

a moderately severe estivo-autumnal malaria and a chronic hookworm infection. Under treatment with quinin he had had no fever since September 10, and apparently was convalescing nicely. Although in a ward in which there were no influenza patients, on the evening of September 22 he had fever and the following morning the symptoms of influenza. From that day on his temperature ranged between 101.4 and 104.4. His pulse and respirations were relatively slow until September 30, the ninth day of his illness, when signs of consolidation were noted over the right lower lobe of the lungs. From then on he rapidly became critically ill, having a pale color and a dark blue cyanosis, death following on the twelfth day of his disease.

Clinical examination of the chest of the average case reveals a very atypical type of pneumonic involvement. Signs of congestion of both lower lobes are found frequently, though in the majority of cases a diffuse process in all the lobes may be present. At the onset, only slightly diminished resonance to percussion may be elicited, with diminished breath sounds and many coarse and fine moist râles. Fluoroscopic examination of the chest at this time reveals little or nothing. But rarely are there signs of pure consolidation of one or more lobes, and then only late in the disease. Frequently there is an abundance of coarse moist râles heard throughout the chest. Rarely are pleural friction sounds elicited. In a very few cases a pleuropericardial rub may be heard. In one instance Major Herrick detected a true pericardial friction, on which sign, together with the roentgenographic evidence, the diagnosis of pericarditis was made, which was confirmed by the necropsy (Fig. 2).

Staphylococcus aureus pneumonia usually pursues a rapid course. Of the patients studied at Camp Jackson, twelve died between the first and fifth day, and seventy-three between the sixth and tenth day of the disease. In Table 1 the onset of the pneumonia was calculated from the onset of the first symptoms of influenza. It will be seen that the average length of the disease was not as long as that of ordinary primary lobar pneumonia. This fulminating character of the infection was likewise noted in the cases studied several years ago in New York.

26-30	2	1.3
31-35	1	0.6
36-40	2	1.3

LABORATORY FINDINGS OF THE DISEASE

The most characteristic feature of this type of pneumonia is the sputum. When typical, the sputum is friable, purulent material of a dirty salmon-pink resembling anchovy sauce or the contents of an overripe furuncle. Occasionally the sputum is hemorrhagic, at first suggesting an acute pulmonary hemorrhage; but on close inspection its purulent character can be distinguished. If smears of such sputum are made and stained according to Gram's method, one sees field after field of gram-positive group cocci and pus cells.

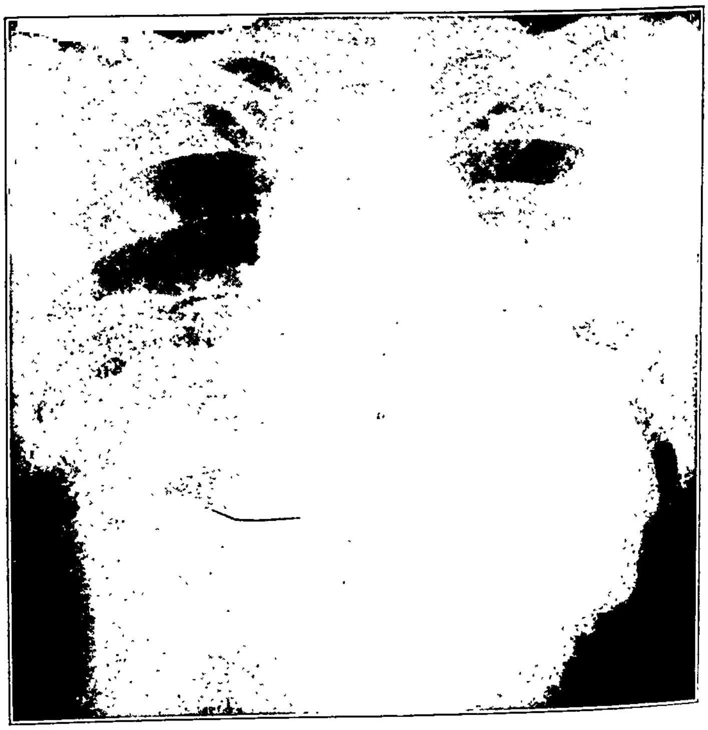

Fig. 2.—Diffuse bronchopneumonia and fibrinopurulent pericarditis; pure Staphylococcus aureus infection.

One can almost give a fatal prognosis when sputum as described above is obtained. Typical sputum, however, cannot always be procured; and frequently cases that ultimately result fatally produce only greenish yellow purulent material which on culture yields the staphylococcus as the predominant organism.

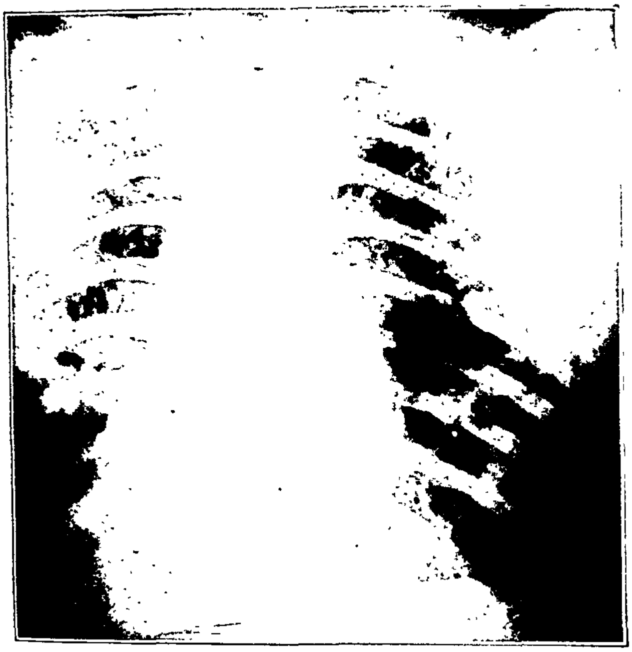

Fig. 3.—Diffuse bronchopneumonia; Staphylococcus aureus and hemolytic streptococcus recovered from the lung.

If sputum containing the staphylococcus is streaked on glucose-free blood agar plates, the colonies appear as opaque, round, shiny disks about 1 mm. in diameter surrounded by a wide zone of hemolysis after eighteen hours' incubation. On removal from the incubator, the colonies may appear white; but if the plates are allowed to remain a few hours in the day or sunlight, the yellow pigment appears.

In the routine examination of hundreds of specimens of sputum, *Staphylococcus aureus* is encountered frequently both from the throats of normal individuals and from those having a definite pneumococcus infection, but not usually as the predominating organism. It is impossible to say what proportion of those having pneumonic lesions and showing *Staphylococcus aureus* in the sputum are harboring the organisms in the alveoli of the lungs. A considerable number of individuals presenting these findings have recovered, but it is doubtful that many of them actually had a staphylococcus infection of the lungs when one considers the pathology of the disease. In many cases, in addition to the predominating *Staphylococcus aureus* in the sputum there were recovered various types of pneumococcus, *B. influenzae*, streptococcus and other organisms. The presence of these bacteria in association with the staphylococcus in the lung was confirmed in many instances in the postmortem examinations.

BLOOD CULTURES

During the height of the epidemic it was possible to make relatively few blood cultures, many of the laboratory staff themselves being ill, and technical difficulties with the culture medium made the possibility of obtaining bacterial growth uncertain. Two cases were reported as having positive cultures. At the Hospital of the Rockefeller Institute, positive blood cultures were obtained in 53 per cent. of the cases of *Staphylococcus aureus* infection. Consequently it is evident that a bacteremia occurs with much greater frequency than with the hemolytic streptococcus infections of the lung, in which it is quite unusual to be able to demonstrate a bacteremia except just before death and then rarely. Only one patient having a positive culture has recovered, to our knowledge, so that the presence of a bacteremia is of very grave import.

PLEURAL FLUIDS

Few cases showed clinical evidence of accumulation of fluid in the chest or pericardium. When present, the fluid was slightly cloudy amber in color, sometimes with a tinge of blood, when discovered early in the disease. If later, frankly greenish-yellow pus may be obtained. Direct smears of the fluid stained by Gram's method show many pus cells and gram-positive group cocci. Many of the bacteria may be seen phagocyted. Cultures of the fluid on plain or blood agar show the typical colony of *Staphylococcus aureus.* The culture plates should be incubated for seventy-two hours before discarding, for frequently when present, the small, colorless, dewdrop-like colonies of *B. influenzae,* which are prone to develop as satellites about the large staphylococcus colony, may escape notice after eighteen hours' incubation, when they are only pinpoint in size and are seen only with a hand lens.

If, by chance, the chest is explored and no fluid is obtained, the needle penetrating solid or semiconsolidated lung tissue, the needle may be washed out by aspirating a little plain bouillon broth culture medium into the syringe and cultures made with the blood-tinged fluid. One can frequently recover *Staphylococcus aureus* in this manner, if it is present.

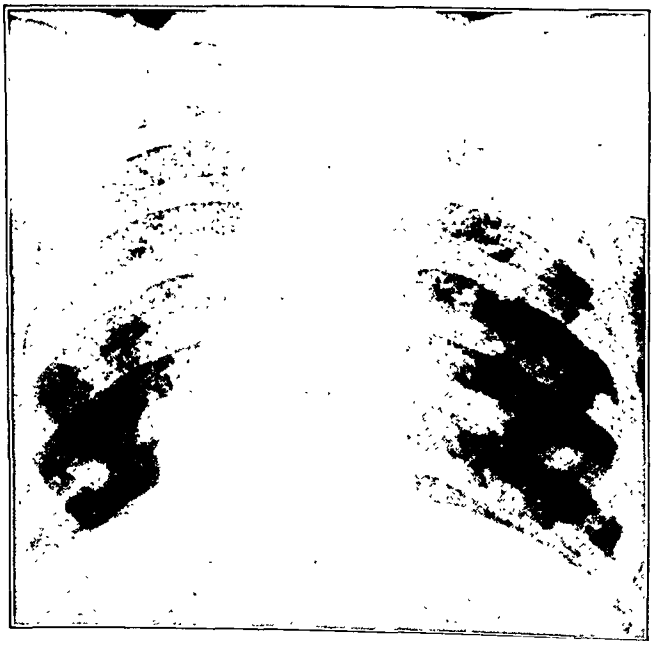

Fig. 4.—Diffuse bronchopneumonia; Staphylococcus aureus and B. influenzae recovered from the lung.

BLOOD EXAMINATIONS

Under the direction of Major M. A. Barber, chief of the laboratory of the base hospital, leukocyte determinations were made of a considerable number of cases of *Staphylococcus aureus* pneumonia.

Table 2 shows the white blood cell estimations of cases grouped according to the results obtained from the postmortem cultures. It is obvious that the majority of the figures are quite unlike those obtained in ordinary lobar pneumonia. Both the patients dying of pure *Staphylococcus aureus* infection and those having a mixed infection with *B. influenzae,* pneumococcus or hemolytic streptococcus, show in many instances a leukopenia. The majority are about normal; a few show a moderate leukocytosis. Many of those having an increased number of white blood cells had localized complications, as empyema or pericarditis, as noted in the table.

It is possible that the cause of the primary epidemic infection, whatever it may be, depresses the hematopoietic system to such a degree that it is unable to react normally to infection by bacteria, which is usually accompanied by a leukocytosis. This, in turn, may offer an explanation for the production of pathologic lesions in the lungs by the bacteria that are commonly found in the nose and throat of healthy individuals and which are to be considered as secondary invaders.

The examination of the urine has shown nothing characteristic of *Staphylococcus aureus* infection, though no special investigation was made of the urine in these cases. A trace of albumin and a few granular casts are frequently seen, as in most acute febrile conditions. Apparently the disease is of so brief a duration that the formation of abscesses in the kidneys rarely takes place.

ROENTGEN EXAMINATIONS[1]

Brief mention has been made of the lack of definite localized shadows in the lungs on fluoroscopic examination early in the disease. Figures 3 and 4 are illustrative of the diffuse involvement of the lungs as shown by roentgenograms. In many instances the diffuse mottling of the whole lung suggests the lesion associated with miliary tuberculosis. In other instances, as in Figures 5 and 6, small multiple areas of consolidation can be demonstrated. Occasionally whole lobes are involved, there being a confluent bronchopneumonia present or a pneumococcus lobar type of lesion with a *Staphylococcus aureus* infection superimposed. The roentgen ray has been of great value as an aid in the diagnosis of the chest complications of this disease, namely, empyema and pericarditis (Figs. 2 and 7).

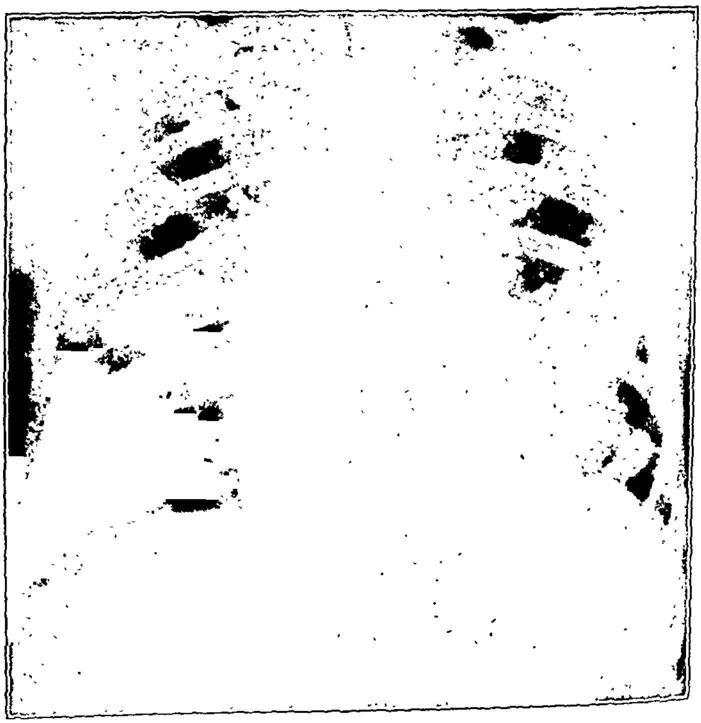

Fig. 6.—Diffuse and confluent bronchopneumonia; Staphylococcus aureus and B. influenzae recovered from the lung.

COMPLICATIONS

In this series of cases the complications have been relatively rare. This has been due largely to the high immediate mortality, the disease running a brief course, death intervening in about ten days and in some cases as early as the fifth day. Only three patients have had discoverable empyema. One of these patients, who had a bacteremia early in the course of the disease, died on the ninth day with a diffuse process in the lungs and a left suppurative pleuritis. The second patient, in addition to a double empyema, had suppurative pericarditis and a bilateral otitis media, and died on the thirty-second day of the disease. The third case was quite unusual, and the patient is convalescing nicely. A large pocket of pus developed in the right chest in the angle between the mediastinum and the diaphragm (Fig. 7). This abscess was drained by resecting a portion of the fifth rib in the anterior axillary line.

---

[1] The roentgen examinations, plates, and photographs were made under the direction of Lieut. G. A. Finney, M. C., U. S. Army, of Kansas, *in charge* of the roentgen laboratory, base hospital, Camp Jackson, S. C.

Fig. 7.—Localized suppurative pleuritis; pure culture of Staphylococcus aureus obtained from pus.

Other complications have been few in number. Seven patients had acute otitis media. One patient had a staphylococcus meningitis. Nine patients had signs of meningeal irritation, but examination of the spinal fluids proved them to be normal. One patient developed a *Staphylococcus aureus* pericarditis. The pericardium, both parietal and visceral layers, were covered with a thick, shaggy coat of fibrin. A small amount of purulent fluid was found in the pericardial sac (Fig. 2).

Subcutaneous emphysema, a complication rarely seen in primary lobar pneumonia, was encountered six times in the total series of about 1,400 cases of pneumonia. In two of these cases *Staphylococcus aureus* was isolated from the lung. The emphysema has been very extensive, involving the head, neck and trunk. In one case the eyelids were completely closed. It apparently embarrassed the respirations but little.

One patient had a complicating suppurative parotitis from which the staphylococcus was cultivated. Several patients had multiple furuncles.

PATHOLOGY

Of the necropsy examinations made during this epidemic by Capts. Paul Wegeforth and W. H. Norton, in fourteen cases it has been possible to cultivate *Staphylococcus aureus* directly from the lung tissue, either as the sole organism or in association with other micro-organisms, as shown in Table 3.

From this material an unusual opportunity has been presented to study the lesions associated with the presence of *Staphylococcus aureus* in the lung tissue. The lungs on gross inspection are not usually so voluminous as those seen in the hemolytic streptococcus infections, nor do they have the same shotty feeling on palpation. Usually the dependent portions of the lungs, the lower lobes or very frequently the posterior portions of all the lobes being the dependent parts with the body in the horizontal position, are involved.

TABLE 3.—LUNG CULTURES IN FOURTEEN CASES

Staphylococcus aureus and Streptococcus hemolyticus	1

There may or may not be any pleural exudate. A fibrinous exudate is much less commonly found than in lobar pneumonia. The surface of the affected portions of the lung is deep purplish blue. If one examines the pleura carefully, one can usually see, in addition to showers of petechiae, small yellowish white spots, pinhead in size, situated just beneath the pleura, which prove to be minute abscesses. The cut surface of the lung may be intensely hemorrhagic, resembling the cut surface of the spleen if the course of the disease has been of brief duration, or it may have the appearance of a confluent bronchopneumonia. One does not see, however, small bronchioles standing up above the cut surface and surrounded by a zone of dark red infiltrated tissue as in the bronchopneumonias following measles, which is the lesion most frequently associated with the hemolytic streptococcus. On the contrary, one usually finds innumerable small ab

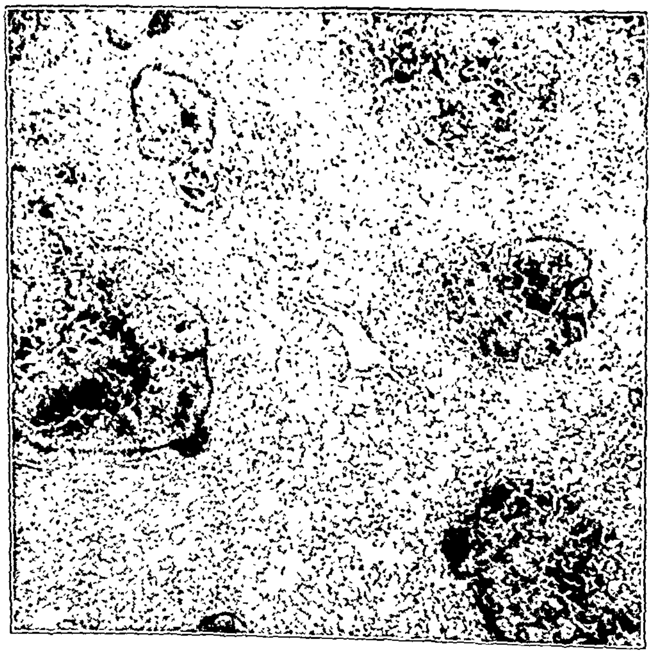

Fig. 8.—Section of lung tissue, ×13, showing abscesses; case from Hospital of the Rockefeller Institute. The photomicrographs were prepared under the direction of Mr. Louis Schmidt, Department of Illustration, Rockefeller Institute for Medical Research, New York.

ranging in size from 1 to 10 mm. in diameter. If the process is a very early one, these minute white spots may not be even broken down. If they are of longer duration, many small abscesses may have become confluent, having softened and become filled with thick, greenish yellow pus. Nine of the fourteen cases examined postmortem revealed these small abscesses. Of the cases not showing abscess formation, three were very early, the patients dying on the fourth, sixth and seventh days from the onset of the primary epidemic infection. The sections of these cases showed intense red cell congestion with rupture of the alveolar walls and exudation of serum and red cells into the alveoli. Another case, in which the patient died on the eleventh day without abscess formation, was complicated by suppurative pericarditis (Fig. 2). In the last case there was a mixed infection with *B. influenzae,* in which process *Staphylococcus aureus* apparently played a minor rôle. Direct smears of the abscesses show pus cells and many gram-positive group cocci. The majority of the abscesses tend to be situated at the periphery of the lung near the pleura, though the whole lung may be involved. The propensity of *Staphylococcus aureus* to form multiple small abscesses in the lung appears to be characteristic of this organism, for the type of lesion shown in Figures 8 and 9 from the case treated at the Hospital of the Rockefeller Institute in 1915 is similar to that illustrated in Figure 10. In the institute case there was no history of any antecedent infection.

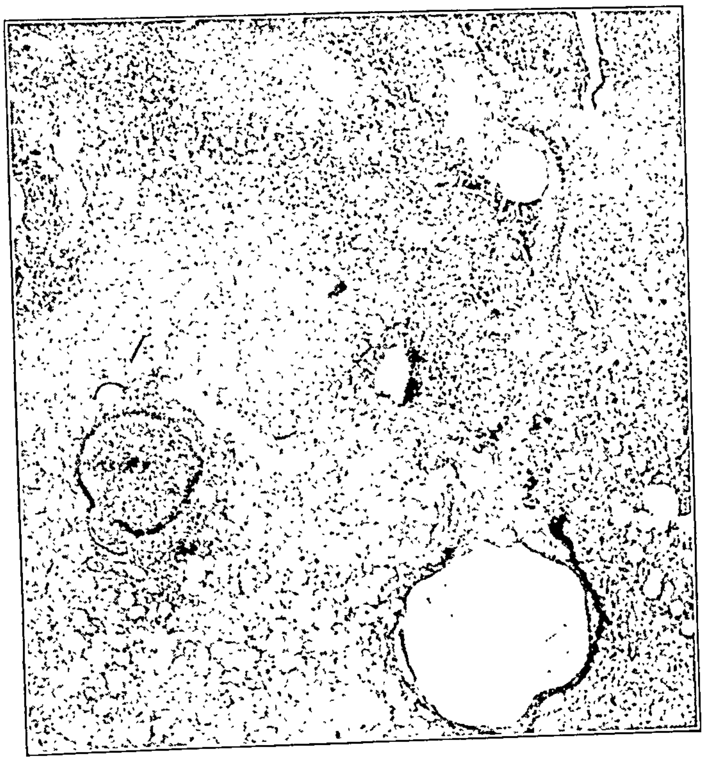

Fig. 9.—Section of lung tissue, ×13, showing abscesses; case from Hospital of the Rockefeller Institute.

Figures 8, 9 and 10 show the circumscribed abscesses found scattered through congested lung tissue. There is at first marked engorgement of the alveolar walls with exudation into the alveoli of serum, a small amount of fibrin, and leukocytes and plasma cells containing blood pigment. There is apparently a very rapid coalescence of alveoli with the resultant formation of small, circumscribed abscesses filled with degenerated pus cells and bacteria (Figs. 10 and 11). In some instances there is an attempt to limit the process by the formation of new connective tissue. In other instances there is so rapid a solution of tissue that this reaction is scarcely evident. Figure 12 shows the lesion rapidly extending out into unaffected alveolar tissue.

Lord,[2] in describing the pathology of the bronchopneumonia following influenza, states that not infrequently small abscesses in the lungs have been found, but no mention has been made of the presence of *Staphylococcus aureus.* In our experience it seems probable that while not every case having a *Staphylococcus aureus* secondary infection in the lung may show abscess formation, the occurrence of innumerable small abscesses of the lung predicates that microorganism, excepting, of course, multiple tuberculous abscesses of the lung, which even grossly present a different pathologic picture.

Three necropsies revealed the presence of a suppurative pleuritis. In one case the pus was localized in the lower part of the left pleural cavity. In another there were collections of pus in both pleural cavities. One of the pockets, situated in the upper part of the left anterior chest, communicated with the pericardial cavity. The latter was the seat of a fibrinopurulent pericarditis.

In this series there were four cases of pericarditis. In one the necropsy disclosed no evidence of infection of the pleural cavities. The heart was covered with a thick layer of shaggy fibrinous material. An acute vegetative endocarditis of the mitral valves was demonstrated in one instance.

Suppuration of the left parotid gland occurred once. In no case did necropsy reveal any abscesses of the kidney, lesions which are frequently seen in *Staphylococcus aureus* pyemia. One abscess in the spleen was discovered.

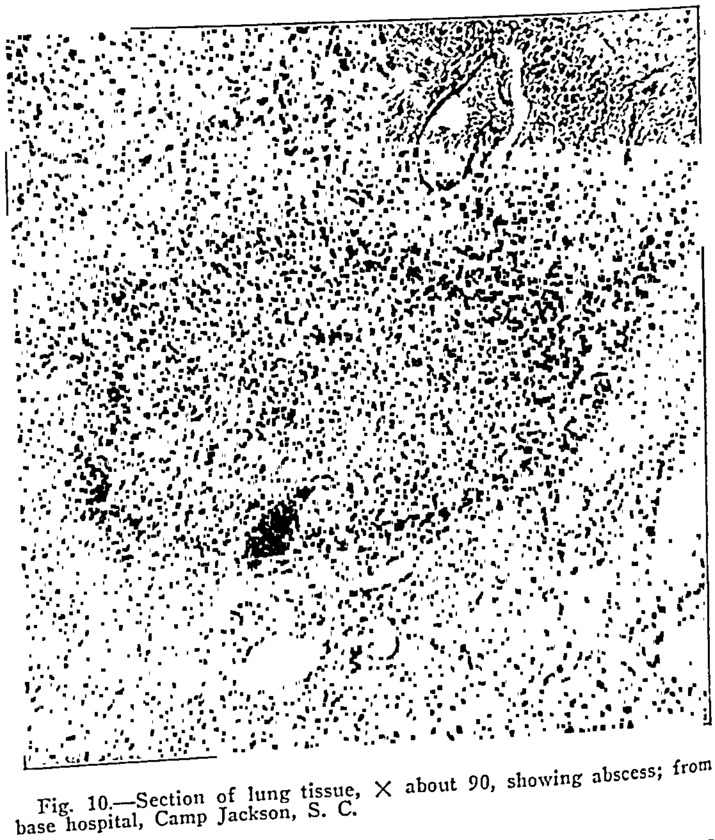

Fig. 10.—Section of lung tissue, × about 90, showing abscess; from base hospital, Camp Jackson, S. C.

A postmortem examination of one of the two cases presenting signs of subcutaneous emphysema was made. It was impossible to discover the pathway of the escape of air from the lungs. The mediastinal tissue was filled with bubbles of air. Along the lappet of the inferior edge of the right upper lobe, the visceral pleura was distended with large bubbles of air varying in size from 1 to 10 mm. in diameter.

---

[2] Lord, in Osler: System of Medicine.

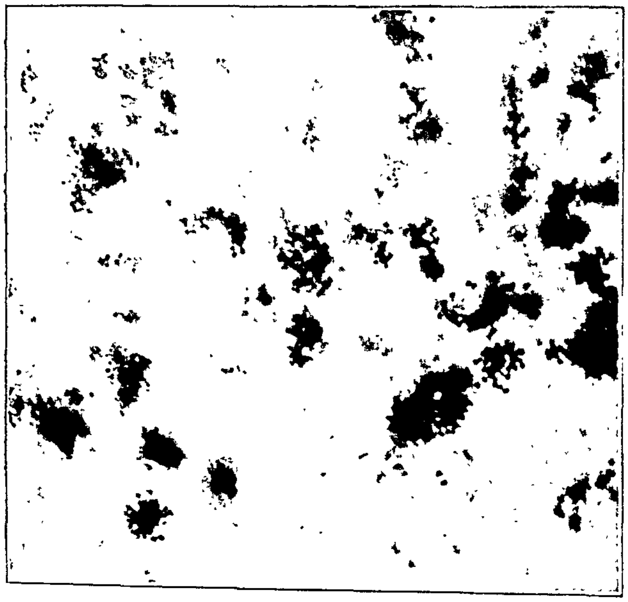

Fig. 11.—Section through a miliary abscess, ×1,000, stained for bacteria, showing group cocci, morphologically staphylococci.

The multiple foci of infection especially numerous in the periphery of the lung, together with the occasional occurrence of metastatic abscesses in other parts of the body, suggest that the condition is disseminated by the blood stream. The absence of abscesses in the liver and kidneys, however, does not support this theory. It is possible that the nonproductive, harassing cough that frequently accompanies the early stage of this epidemic infection was responsible for the dispersion of micro-organisms from the nose and throat into the deeper respiratory passages.

POSTMORTEM CULTURES

On account of the crowded condition of the morgue, it became impossible to hold many postmortem examinations. Consequently an attempt was made to learn more of the bacterial infection of the lungs of the fatal cases by exploring the lungs postmortem with an ordinary chest exploring needle and syringe. The syringes and needles were sterilized by boiling and the skin by the application of tincture of iodin. The needle was thrust into the lung tissue and aspiration continued until about 1 c.c. of bloody fluid was obtained. This fluid was then cultivated on glucose-free blood agar plates and slants and in plain broth, and in many cases direct smears of the lung juice were made. These smears checked closely with the cultures. Table 4 details the results of these postmortem cultures. The organisms recovered in this way were found as well in the sputa, blood cultures, and empyema fluids. The number of mixed infections of the lung is surprising. But Cole and MacCallum,[3] in a study of the bacteriology of cases of bronchopneumonia following measles last winter at San Antonio, Texas, obtained similar results.

The occurrence of *Staphylococcus aureus* in the lungs in the fatal cases is quite striking, 49 per cent. of the 312 cases cultivated showing this organism present either alone, ninety-two cases, or in association with the influenza bacillus, twenty-two cases, the pneumococcus, twenty-nine cases, or various streptococci, twelve cases. In many instances, death was early predicted from the appearance of the sputum alone, and the postmortem cultures verified the information obtained from the sputum examination.

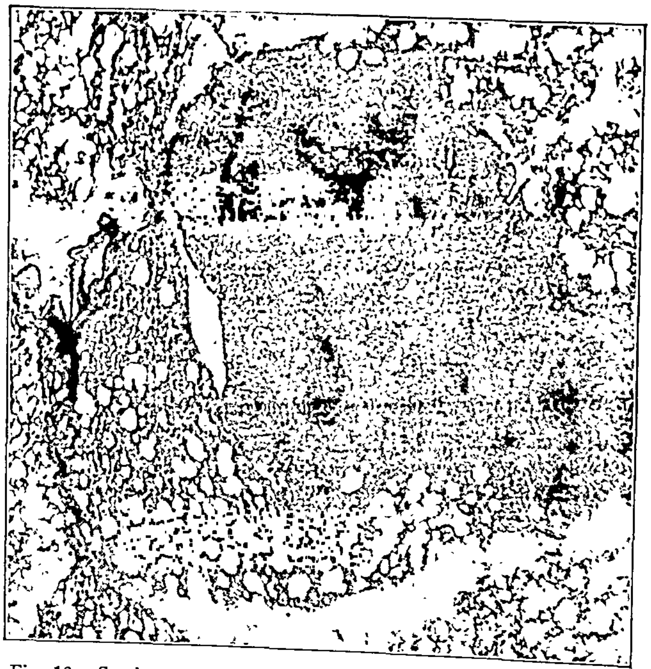

Fig. 12.—Section of lung tissue, showing a type of rapidly spreading lesion.

---

[3] Cole, R., and MacCallum, W. G.: Pneumonia at a Base Hospital, J. A. M. A. 70: 1146 (April 20) 1918.

The ninety-four cases showing the pneumococcus alone in the lungs were clinically more like typical lobar pneumonia, often showing extensive consolidation and pure bronchial breathing.

It is to be remarked that the organism found so frequently last winter associated with the bronchopneumonia following the epidemic of measles in the Army camps, the hemolytic streptococcus, was rarely encountered either in the sputum or in material from the lung.

On several of the plates, colonies of bacteria conforming to the characteristics of the meningococcus were found. Unfortunately, in only one case did these colonies grow on subcultures, and in this instance the organism agglutinated with Strain 10 meningococcus antiserum furnished by the Rockefeller Institute. This patient died without exhibiting any symptoms of meningitis that could be detected clinically. The presence of these organisms in the lungs, and the occurrence of several cases of meningococcus meningitis complications in this series of cases, opens up a new aspect to the ever increasing knowledge of the activities of the meningococcus in the human body.

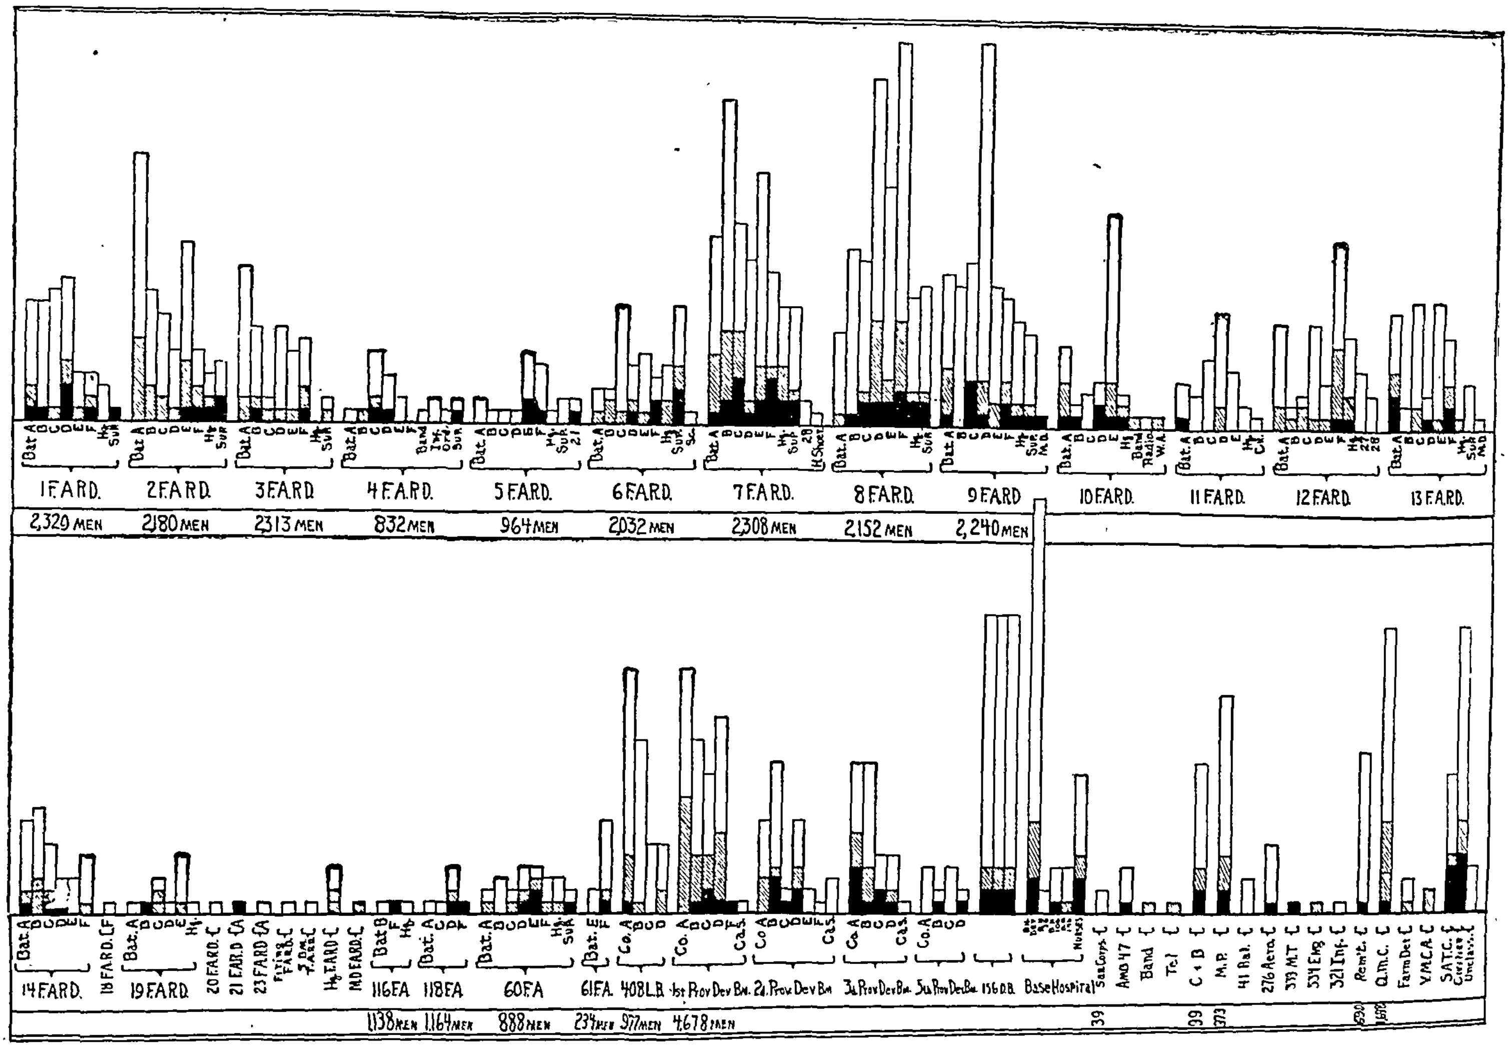

Fig. 13.—Incidence of pneumonia in military organizations at Camp Jackson, *Sept. 15 to Nov. 1, 1918; outline, total cases of pneumonia;* one square represents one case; black, Staphylococcus aureus deaths; shaded, deaths associated with other organisms.

In two cases, organisms conforming culturally and morphologically to bacilli of the hemorrhagic septicemia group were encountered. The colonies were moist and grew readily on blood agar. They appeared as gram-negative oval coccobacilli frequently showing bipolar staining. Some of the slides were examined by Major M. A. Barber, who has had a field experience with the bacillus of plague, and he observed the close morphologic similarity of these organisms to the plague bacillus. Once before this organism was encountered in a fulminating case of bronchopneumonia treated at the Rockefeller Institute Hospital. Here again, it was found associated with *Staphylococcus aureus.*

EPIDEMIOLOGY

Pneumonia associated with *Staphylococcus aureus* occurred in almost every organization at Camp Jackson (Fig. 13). In general, where the total incidence of pneumonia was high there was a correspondingly larger number of *Staphylococcus aureus* infections.

In the First, Second and Third regiments, Field Artillery Replacement Depot, with a total strength of 6,820 men, there developed 178 cases of pneumonia, in which fourteen were found to be harboring *Staphylococcus aureus* in the lung, a percentage incidence of 7.8. In the Seventh, Eighth and Ninth regiments, F. A. D. R., organizations having a smaller quota, 6,700 men, there were 380 cases of pneumonia, in forty-three, or 11.3 per cent., of which, staphylococci were harbored in the lung.

In the base hospital organizations there occurred fifty-eight cases of pneumonia, of which seven, or 12 per cent., were associated with *Staphylococcus aureus.*

The higher incidence of pneumonia in the Seventh, Eighth and Ninth regiments may possibly be explained by the fact that these regiments were composed of men who were recent arrivals in camp and in the midst of their period of intensive training.

Last winter in the mortality statistics of the postmeasles bronchopneumonias in the Army, which were largely due to the hemolytic streptococcus, certain Southern states suffered in comparison with the Northern states.

In this camp the incidence of the virulent *Staphylococcus aureus* pneumonia was greater among the men from New York and Ohio, 15 and 18.5 per cent., respectively, than among the men from Florida, 12.5 per cent., North Carolina, 9 per cent., and South Carolina, 12 per cent. Here again the men from Ohio and New York were among the more recent arrivals.

South Carolina furnished ten *Staphylococcus aureus* pneumonias, or 7.1 per cent. of the 139 pneumonias among the negroes. These men were from one regiment of the F. A. R. D. and from labor battalions, and had been in camp for some time.

caffein and whisky were also used. Hypodermoclysis or infusions of physiologic sodium chlorid solution were administered in the event of the patient's not being able to take fluids by mouth. In a few cases, infusions of 25 per cent. glucose in physiologic sodium chlorid solution, in 250 c.c. amounts, were given once or twice a day. Practically no amelioration of the patient's condition followed the use of these therapeutic measures.

In the treatment of the complications, the one patient having a localized suppurative pleurisy was drained by a thoracotomy and costectomy and the Carrel-Dakin after-treatment instituted with excellent results. The other two patients died with complicating pericarditis and endocarditis.

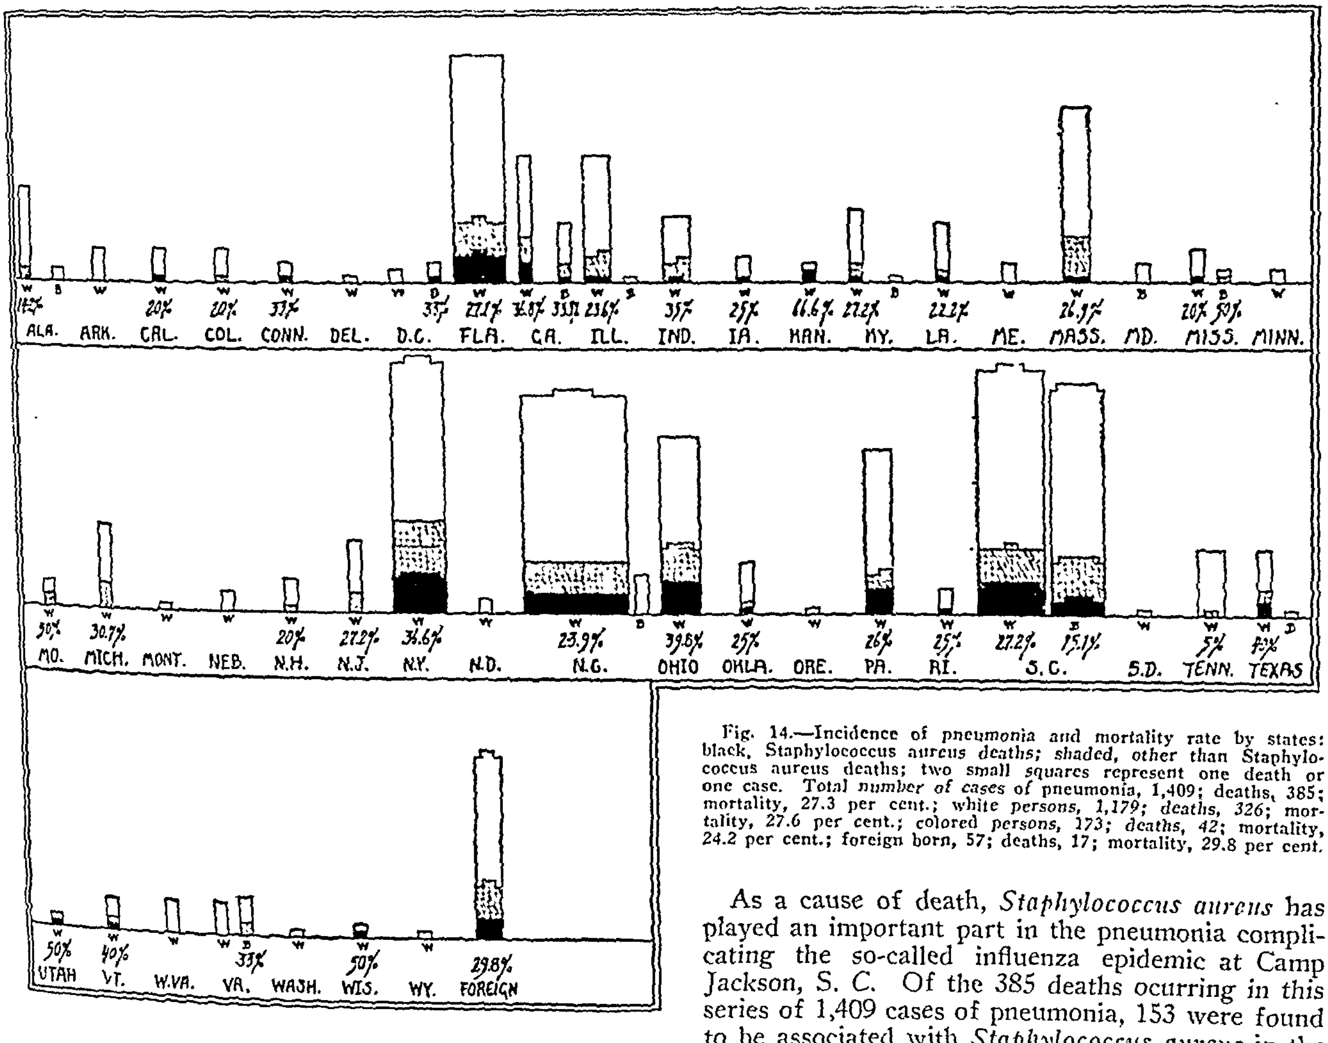

Fig. 14.—Incidence of pneumonia and mortality rate by states: black, Staphylococcus aureus deaths; shaded, other than Staphylococcus aureus deaths; two small squares represent one death or one case. Total number of cases of pneumonia, 1,409; deaths, 385; mortality, 27.3 per cent.; white persons, 1,179; deaths, 326; mortality, 27.6 per cent.; colored persons, 173; deaths, 42; mortality, 24.2 per cent.; foreign born, 57; deaths, 17; mortality, 29.8 per cent.

TREATMENT

The treatment of *Staphylococcus aureus* infection of the lung is extremely ineffectual. Apparently unless the lesions become localized, as happened in two of the cases at the Hospital of the Rockefeller Institute, or there is a localized empyema, the outlook for recovery is extremely bad. The soldiers treated at Camp Jackson were put to bed as soon as possible after they became ill. They were not allowed to get out of bed or to sit up. Very little catharsis was given, dependence being placed on a daily morning enema of soapsuds to keep the bowels open.

As a routine for pneumonia, tincture of digitalis was given in 2 c.c. doses every four hours up to 20 c.c., and continued further if indicated. Camphor in oil,

As a cause of death, *Staphylococcus aureus* has played an important part in the pneumonia complicating the so-called influenza epidemic at Camp Jackson, S. C. Of the 385 deaths ocurring in this series of 1,409 cases of pneumonia, 153 were found to be associated with *Staphylococcus aureus* in the lung. As cultures from the lung were obtained from only 312 of the 385 individuals who died, it is reasonable to suppose that this number does not represent the total mortality due to this micro-organism.

The striking features of the disease are the peculiar cherry-red indigo-blue cyanosis, the fulminating course, the lack of definite signs of consolidation of the lungs, the dirty salmon-pink purulent sputum, and usually a leukopenia.

Pathologically, if the disease is of long enough duration, it is characterized by innumerable abscesses in the lungs.

The prognosis is always grave, though a few patients occasionally survive. Only two patients in this series have recovered.

From the standpoint of our present knowledge, it would seem probable that the particular *Staphylococcus aureus* found in the lungs of these cases was no other than that found often in the mouth secretions of healthy persons. However, the depression of the individual's defensive mechanism by the primary epidemic infection was sufficient to enable these organisms subsequently to produce widespread pulmonary lesions. This, in turn, explains the occurrence of the infection in almost every organization in Camp Jackson and a higher incidence of the infection among the more recent arrivals in camp, irrespective of the states from which they came.

EARLY SUTURING OF WOUNDS OF THE FACE

V. H. KAZANJIAN
Major; Surgeon, Harvard Surgical Unit
B. E. F., FRANCE

The practice of suturing wounds of the body at an early date after injury is at present arousing an active interest among surgeons. The procedure is achieving increased success, undoubtedly because of a better knowledge of the exact nature of war injuries, of a better surgical technic involved, and of a proper use of antiseptics.

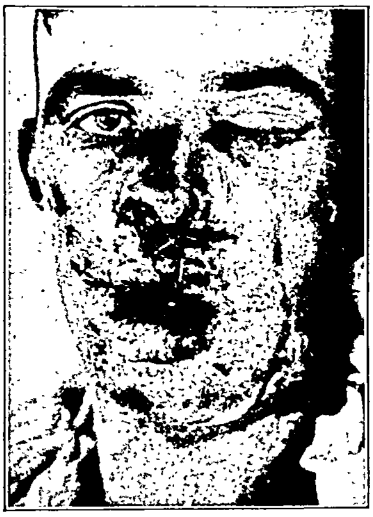

Fig. 1 (Case 1).—Appearance of patient, Aug. 27, 1917, after wound had been closed at a casualty clearing station.

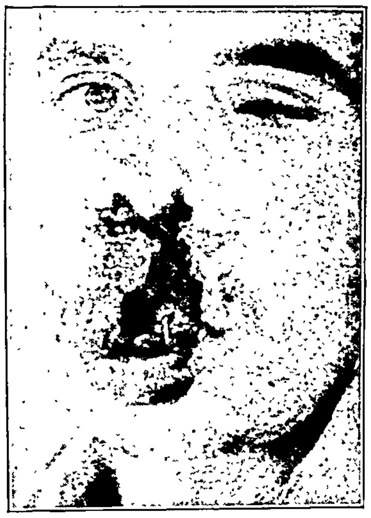

Fig. 2 (Case 1).—Septic condition of tissues and failure of sutures, September 7.

If early suturing can be accomplished, the benefits are obvious: the healing process is materially shortened, many unsightly scars are avoided, and the patient undergoes a briefer period of convalescence.

There has always been a considerable divergence of opinion in regard to the most suitable time for the closure of facial wounds. Some surgeons have recommended early suturing on the grounds that undue contraction of the tissues was forestalled by bringing the lacerated borders together and that subsequent elaborate plastic operations were to a great extent evaded. Others favored late suturing at a time when the wounds were clean, asserting that suppuration and inflammation were greater hindrances than contraction of the tissues to a successful cosmetic effect. A critical analysis of the two opposing views points to the fact that both methods must be followed to obtain a minimum amount of facial disfigurement. The determining factors are the location and severity of the wounds, the amount of involvement of adjacent structures, and the degree of sepsis that has developed.

The vascularity of the facial tissues unquestionably promotes rapid healing and an early reduction or disappearance of inflammation; yet the advantage is partly offset by these conditions:

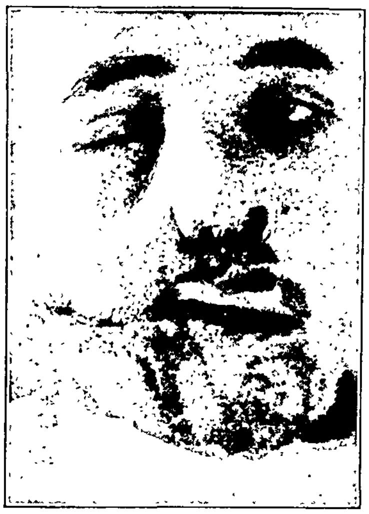

Fig. 3 (Case 2).—Result of operation at a casualty clearing station, June 25, 1917.

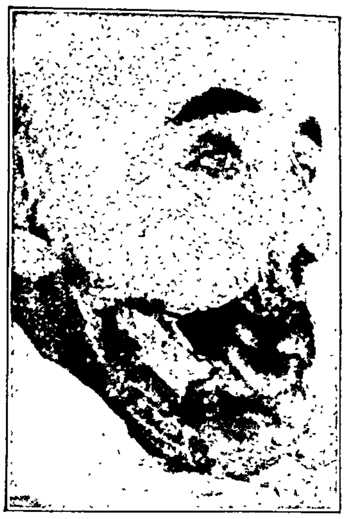

Fig. 4 (Case 2).—Appearance of patient, June 28.

The majority of wounds communicate with the nasal or oral cavities, from which they cannot be isolated, and they are therefore easily and persistently reinfected.

Serious injuries are always associated with a comminution of the bone tissue, the displacement of which exaggerates the size of the wound, favors the inflammation, and facilitates the spread of sepsis.

Liberal excision of the soft tissues, which is an essential feature in the technic of primary suturing of wounds in other parts of the body, is obviously impracticable on the face.

PRIMARY SUTURING

Primary suturing of wounds of the face has been practiced frequently at casualty clearing stations, but the results, as observed at many base hospitals, would lead to the belief that the procedure is totally unsatisfactory and would continue to be so, unless modifications in technic and a careful selection of suitable cases were made. Only in mild and superficial cases has healing taken place, and when the damage to the

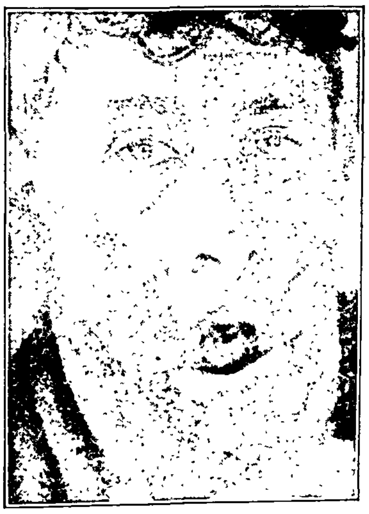

Fig. 5 (Case 3).—Appearance of patient, Sept. 23, 1917, after suturing of wounds at a casualty clearing station.

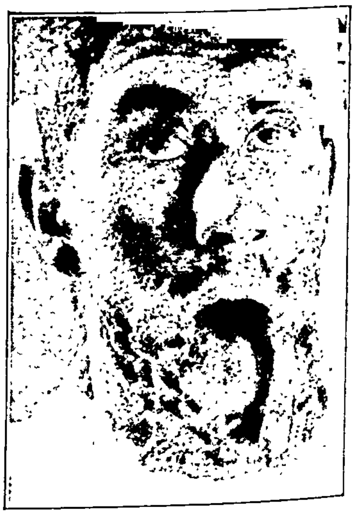

Fig. 6 (Case 3).—Resulting condition, September 27.

soft tissues has been associated with bony injury, the attempted closure has ultimately given way, and brought on added inflammation, sepsis, sloughing, and discomfort to the patient.

Aside from the problem of merely averting a deformity in cases of gunshot wounds of the face and jaws, there remains the necessity of avoiding fatal complications, of establishing drainage, and of restoring function. The treatment of the bony parts cannot at any stage be dissociated from suturing or plastic operations. The shape and expression of the human face depends on the proportional development of the bony substructures; when this framework has been mutilated, its reconstruction is the first essential step in the restoration of facial appearance. And if the bone has suffered pronounced loss, suturing or plastic operations can be performed only with artificial substitutes for this framework.

Bearing in mind that sepsis, fractures and the loss of natural support are obstacles to successful primary suturing of wounds of the face, one will see that hastily conceived operations really accomplish nothing, for if the stitches fail, the progress of the patient has been retarded, while if they hold, the deformity and the suppuration are likely to be intensified.

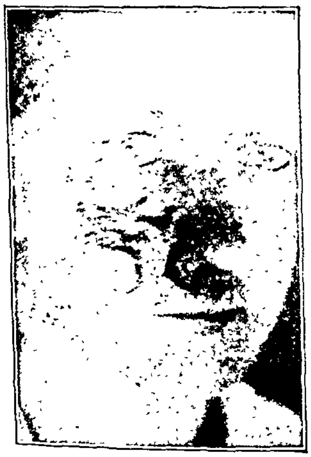

Fig. 7 (Case 4).—Appearance of patient on admission, Aug. 2, 1916.

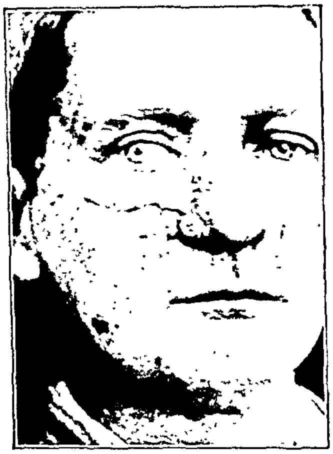

Fig. 8 (Case 4).—Condition on evacuation, August 20.

Cases 1, 2 and 3—unfortunately representative of a large number—demonstrate the results of injudicious primary suturing in cases of extensive wounds:

Case 1.—Private H., wounded, Aug. 24, 1917, and admitted to the hospital, August 26, had been hit by pieces of metal which had destroyed a portion of the upper lip and caused wounds of the right cheek, right half of the lower lip, and the nose. The left eye also was injured. In the upper jaw the teeth and alveolar process of the right side and anterior region were destroyed, and in the lower jaw there was a comminuted fracture in the right bicuspid region, accompanied by loss of all teeth on the right side except the second molar. The wound had been completely closed at a casualty clearing station, as seen in a photograph taken on August 27 (Fig. 1). The tissues were extremely septic, and the sutures had failed, as shown in Figure 2, of September 7.

Case 2.—Private L., wounded, June 22, 1917, and admitted to the hospital, June 24, had lost considerable soft tissue of the upper lip, and in addition the wound radiated to the right cheek and chin. A large amount of alveolar process and bone, together with all teeth from the right tuberosity of the maxilla to the left cuspid, had been destroyed. In the lower jaw the comminution and loss of the teeth extended from the right angle to the left cuspid. The result of operation at a casualty clearing station is shown in Figure 3 (photograph taken June 25), and the appearance on June 26 is seen in Figure 4.

Case 3.—Second Lieutenant A., wounded, Sept. 20, 1917, and admitted to the hospital, September 22, had a lacerating wound of the lower lip, right cheek and chin which involved no appreciable loss of soft tissue. The comminution of the mandible extended from angle to angle with pronounced displacement of the fragments and a considerable loss of bony tissue. The wounds had been sutured at a casualty clearing station, as shown in Figure 5 (photograph taken September 23), but the resulting condition, September 27, is illustrated in Figure 6.

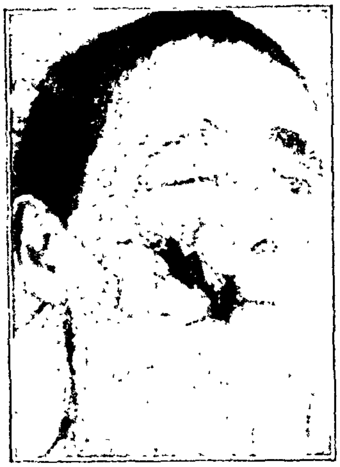

Fig. 9 (Case 5).—Appearance on admission, June 13, 1917.

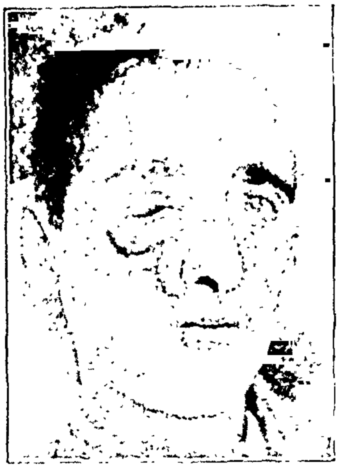

Fig. 10 (Case 5).—Condition on evacuation, July 6.

Certain kinds of wounds, however, appear to respond favorably to primary suturing at advanced units. Superficial wounds with no loss of soft tissue, and also those with slight or no connection with the oral or nasal cavities, in most instances may be closed successfully. The lip borders and also the nose, being delicate and weakly supported, often unite after injury in an unnatural approximation with nearby tissue, and if conditions allow their proper location by operation at an early stage, the benefit is appreciable.

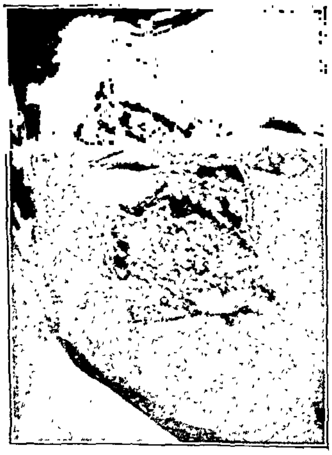

Fig. 11 (Case 6).—Appearance on admission, Aug. 8, 1916; traces are visible of early suturing prior to admission, successful only at the margin of the upper lip.

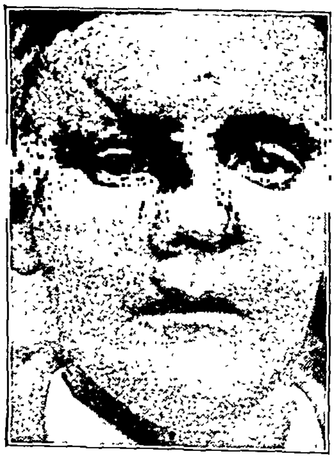

Fig. 12 (Case 6).—Condition on evacuation, September 29.

While, however, steps may have been taken on the one hand to improve the appearance of the face, on the other the individual may have been harmed in other ways. The need of avoiding a general anesthetic cannot be overemphasized when the patient is suffering from gunshot wounds of the face and jaw, for the presence of sepsis in the oral cavity only too often leads to respiratory complications. From our experience, a very high percentage of deaths from bronchopneumonia have given a previous history of the administration of a general anesthetic.

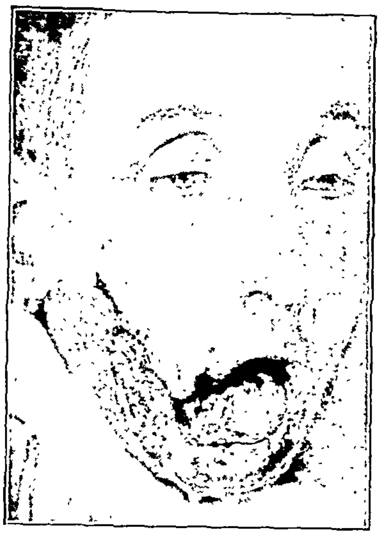

Fig. 13 (Case 7).—Appearance on admission, March 20, 1917.

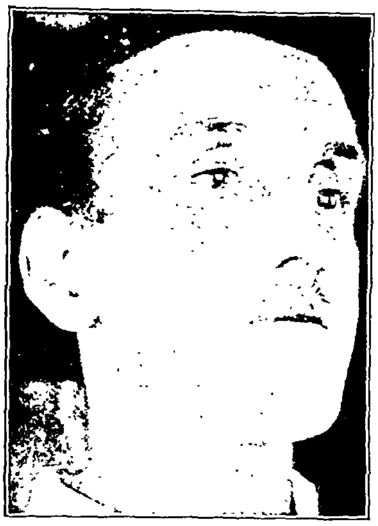

Fig. 14 (Case 7).—Condition on evacuation, August 14.

If suturing is attempted, it should be invariably under a local anesthetic, not only because it evades the occurrence of complications, but also because the area affected by the injury is often so reduced in sensitiveness that anesthesia is gained by small amounts of procain in conductive or infiltrative injections.

EARLY SECONDARY SUTURING

While there does not appear to be more than a limited field for primary suturing, there is broad scope for early secondary suturing. Most cases have been done between the fifth and twelfth day after injury, depending on the nature of the wound, the condition of the patient, and the severity and duration of the infection. Fixation of the bony fragments and a control of sepsis *always* precede the operation. The types are:

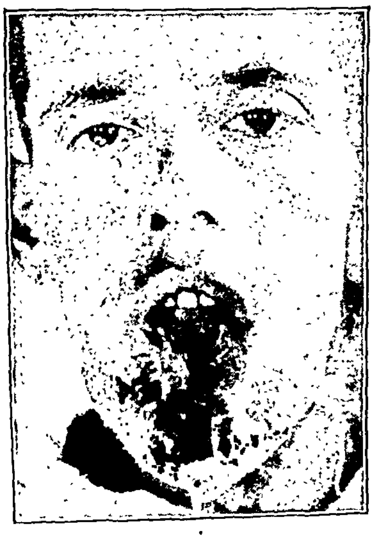

Fig. 15 (Case 8).—Appearance on admission, Sept. 22, 1917.

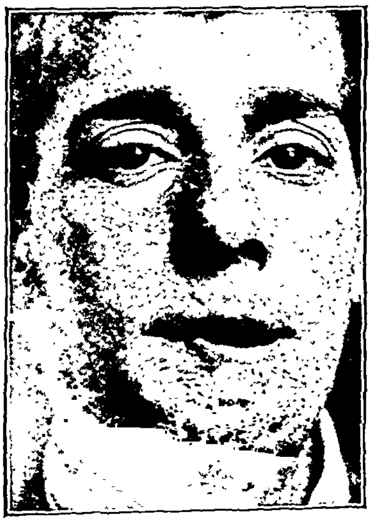

Fig. 16 (Case 8).—Condition on evacuation, Oct. 30.

(*a*) Wounds in which there is slight or no bony injury.

(*b*) Wounds involving extensive bony injury *without loss* of soft tissue.

(*c*) The radiating parts of certain wounds, as a definite step in preparation for a later plastic operation.

In all cases the preliminary treatment of the injuries is directed to reduce the inflammation and edema as soon as possible by fomentations and frequent dressings with eusol (a solution prepared by mixing chlorinated lime, 12.5 gm., and boric acid, 12.5 gm., with water to make 1 liter, and filtering). The oral cavity and wounds are syringed freely and frequently with antiseptic solutions—such as potassium permanganate or boric acid—and adequate drainage is maintained. Then, when the wound appears clean, suturing is attempted, with special precaution to avoid tension by the use of sliding skin flaps or the undermining of the adjacent surfaces. It is often advisable to leave a small portion open to continue the proper drainage.

WOUNDS WITH SLIGHT OR NO BONY INJURY

Case 4.—Private M., wounded, July 30, 1916, and admitted to the hospital, August 2, had a wound of the right cheek and also of the nose with some laceration (Fig. 7). No comminution from the wound to the antrum, nasal cavity, or mouth had been caused, but the upper jaw as a whole was fractured without displacement or complication. August 10, the soft tissues were practically free from sepsis and were sutured. The condition of the wound on evacuation of the patient, August 20, is shown in Figure 8.

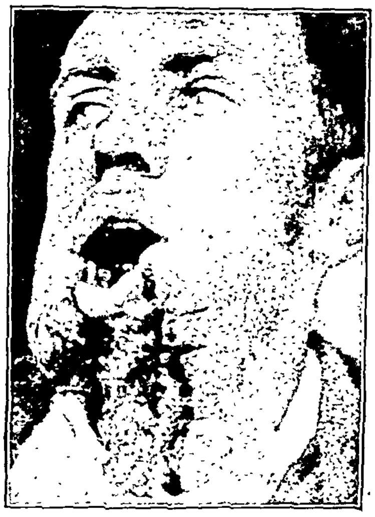

Fig. 17 (Case 9).—Appearance on admission, June 30, 1917.

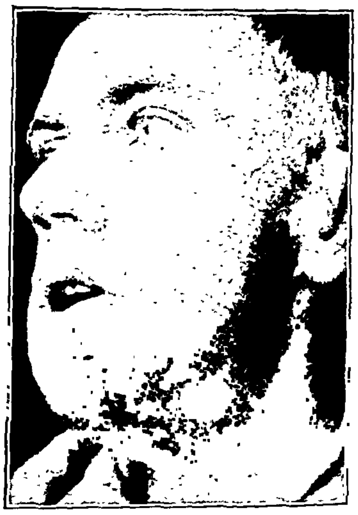

Fig. 18 (Case 9).—Condition on evacuation, October 14.

Case 5.—Private D., wounded, June 10, 1917, and admitted to the hospital, June 13, had an extensive lacerating wound of the right cheek (Fig. 9). The superior maxilla as a whole was fractured without comminution or displacement, and there was a simple fracture of the right ascending ramus of the mandible, without complicating factors. A small opening led to the right antrum, which, in turn, drained intra-orally at the upper right biscuspid region. The wound was closed, June 27. The right eye had been enucleated, June 15, under a general anesthetic, and it was necessary to allow slight drainage at the upper end of the wound. On evacuation, July 6, the suppuration had practically ceased. The facial appearance is shown in Figure 10.

Case 6.—Private De., wounded, Aug. 5, 1916, and admitted to the hospital, August 8, had superficial wounds of the right supra-orbital region, cheek, nose and upper lip (Fig. 11). There was only slight bony injury to the nose. By August 26, the wounds were clean and sutured (by Major Wheeler). An external appliance was used immediately to maintain the position of all soft parts during the process of healing. September 10, a slight correction was made in the left ala of the nose. The patient was evacuated, September 20, as shown in Figure 12. The first photograph (Fig. 11) shows traces of early suturing prior to admission, which was successful only at the margin of the upper lip. Failure may be attributed to sepsis and to excessive tension on the sutures, which in the later operation was avoided by appliances.

WOUNDS INVOLVING BONY INJURY

Wounds involving bony injury vary extensively in regard to the severity and amount of destruction. They all suppurate freely, and the inflammation is marked. The early treatment is directed toward the reduction of sepsis and swelling by the use of frequent irrigation and fomentations. All irritating and *useless* fragments of bone or teeth are removed, splints for the reduction of the fracture applied, and appliances in certain instances also used to support the soft tissues.

Suturing is not attempted until the inflammation has disappeared from the parts, and then the entire wound is not always closed, since abundant suppuration takes place from within the oral cavity from the injured bone.

Cases 7 to 11 illustrate this condition:

Case 7.—Private T., wounded, March 17, 1917, and admitted to the hospital, March 20, had a small wound of entrance in front of the left ear and a large wound of exit on the right cheek involving the angle of the mouth. There was no appreciable loss of soft tissue (Fig. 13). About three fourths of the maxilla, and all the teeth and alveolar process, were destroyed, resulting in perforation of both hard and soft palate. Various mechanical supports were used to mold the palate, and April 1, the wound was sutured. The patient was supplied with oral restorations and evacuated, August 14, as shown in Figure 14.

Case 8.—Private H. T., wounded, Sept. 20, 1917, and admitted to the hospital, September 22, had a large vertical wound of the lower lip and chin (Fig. 15). In the lower jaw there was comminution with much loss of bone between the bicuspid regions. A lower metal splint was adjusted, October 3. The wound appeared clean, October 7, and was sutured. The patient was evacuated, October 3, as seen in Figure 16.

Case 9.—Gunner C., wounded, June 27, 1917, and admitted to the hospital, June 30, had a large wound extending from the lower lip to the chin, sublingual region and neck (Fig. 17), but there was no appreciable loss of soft tissue. The mandible was severely comminuted from the left to the right molar regions. The loss of mandibular continuity at the symphysis was about 1 inch. July 8, several fragments of necrotic bone were removed, and a splint was adjusted to immobilize the remaining portions of the mandible. July 15, the wounds were clean and were sutured. October 9, certain scars and folds in the submaxillary region were removed. The patient was supplied with a temporary plate and evacuated, October 14 (Fig. 18).

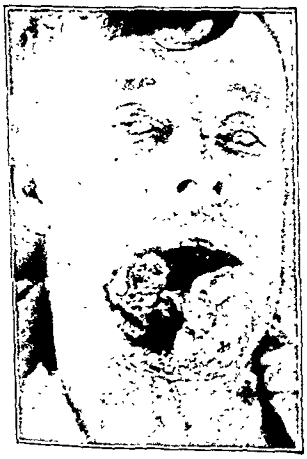

Fig. 19 (Case 10).—Appearance on admission, June 12, 1917.

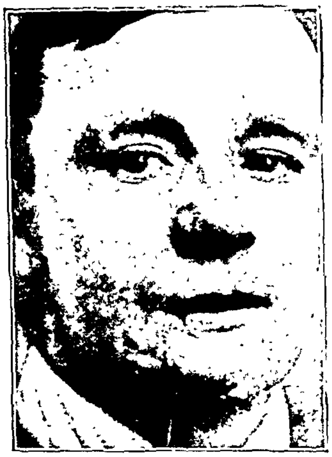

Fig. 20 (Case 10).—Condition on evacuation, November 19.

Case 10.—Private B., wounded, June 10, 1917, and admitted to the hospital, June 12, had a large wound of the lower lip, right side of the chin and submaxillary region (Fig. 19). The mandible was severely comminuted from the median line to the right second molar. June 17, a lower metal splint was fitted. June 27, the wound was sutured. October 17 and 29, small incisions were made in the submaxillary region for drainage and abscesses. November 1, scars on the face were excised, and on November 19 the patient was evacuated (Fig. 20).

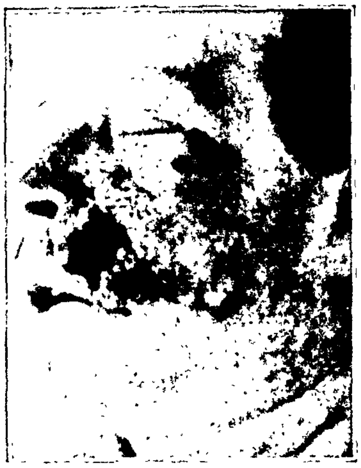

Fig. 21 (Case 11).—Appearance on admission, Feb. 1, 1916.

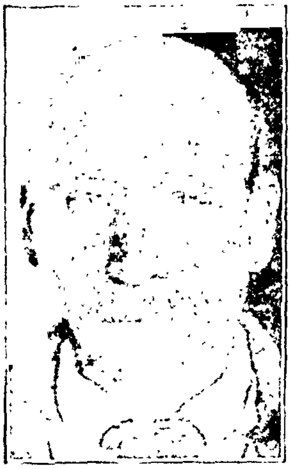

Fig. 22 (Case 11).—Condition on evacuation, June 6.

Case 11.—Private A. M., wounded, Jan. 29, 1916, and admitted to the hospital, February 1, had been hit by a bullet which entered anterior to and above the left angle of the mandible. There was a wound of exit which lacerated the tissues of the left upper lip and cheek to the left of the nose (Fig. 21). The mandible was uninjured. The maxilla was severely lacerated and all teeth were destroyed except the right molars and the right central, lateral and cuspid. The bone carrying these three teeth was very loose. The palate was about one half lost. February 17, the useless teeth and pieces of bone were removed. February 12, a vulcanite splint was adjusted to mold the palate vault and to immobilize the anterior segment of the maxilla. The wound was sutured on the same date. A denture was supplied and the patient was evacuated, June 6 (Fig. 22).

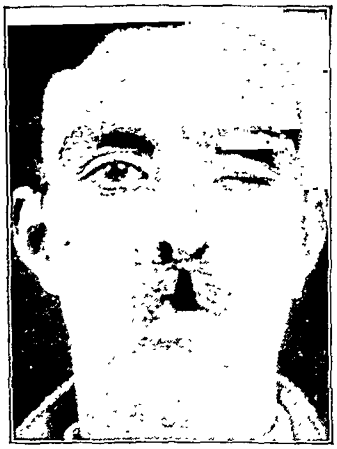

Fig. 23 (Case 1).

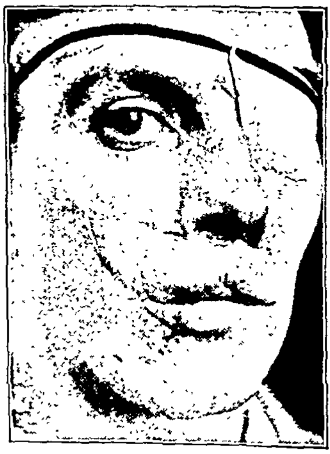

Fig. 24 (Case 1).—Condition on evacuation, Feb. 24, 1918.

WOUNDS INVOLVING EXTENSIVE DESTRUCTION OF THE SOFT TISSUES

The reconstruction of a part of the face must invariably be postponed until all suppuration has disappeared and the wound is in a healthy condition. It then demands a careful planning of flaps and appliances. The success of the final operation is augmented by the careful preliminary treatment, by the control of scar formation, by perhaps judicial early secondary suturing only of certain radiating parts, and by the maintenance of the oral cavity in a condition suitable for appliances or later oral restorations.

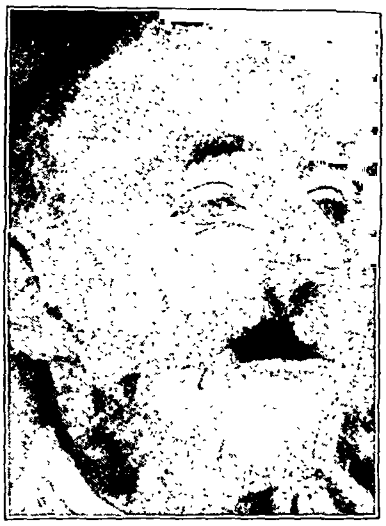

Fig. 25 (Case 2).

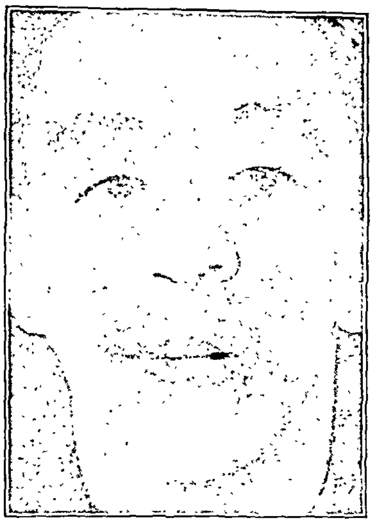

Fig. 26 (Case 2).—Condition on evacuation, March 23, 1918.

To illustrate examples of this type, the completed histories of Cases 1, 2 and 3 are given:

Case 1 (Continued, Fig. 23).—Sept. 2, the mouth was cleared of the remaining useless teeth and alveolar process, and September 8 a lower metal splint was used to immobilize the mandible. September 10, the portion of the wound radiating to the right cheek was sutured, and on the following day, upper and lower vulcanite splints, designed to maintain the facial contour, were adjusted. December 29, the upper lip was reconstructed. Feb. 12, 1918, dentures were inserted. January 26 and February 19, operations were performed to modify the shape of the mouth and lips, and to remove scars. On evacuation, February 24 (Fig. 24), the lower jaw was united, and the remaining bony tissue and mucous membrane of the maxilla was in a healthy condition.

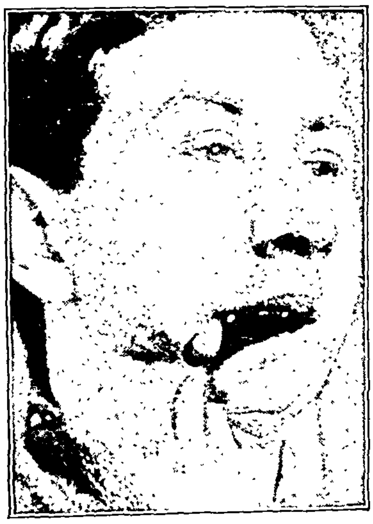

Fig. 27 (Case 3).

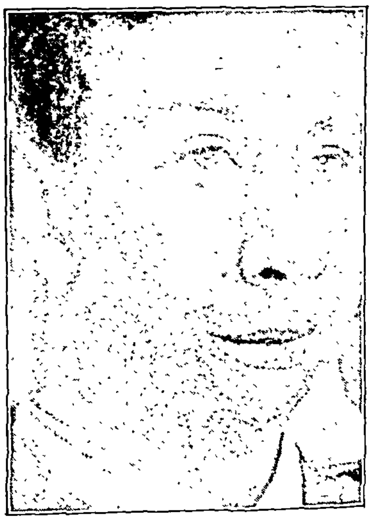

Fig. 28 (Case 3).—Condition on evacuation, April 2, 1918.

Case 2 (Continued, Fig. 25).—July 7, there was a hemorrhage from the right antrum, which did not recur after packing. Vulcanite intermaxillary splints were fitted, July 12. July 14, that portion of the wound which radiated to the cheek was sutured. The upper lip was reconstructed, October 1. July 17 and 19, 1917, and Jan. 25 and March 12, 1918, smaller corrective operations were performed, following the two major plastic operations. Dentures were supplied and the patient was evacuated, March 23 (Fig. 26). The lower jaw was united and the mucous surfaces of the upper jaw were in a healthy condition.

Case 3 (Continued, Fig. 27).—Oct. 4, 1917, a lower metal splint was fitted. November 3 and 5 and December 27, certain pieces of necrosed bone and useless teeth were removed. A vulcanite intermaxillary splint was inserted, November 21, which served to give the requisite fulness to the lower lip. Plastic operations were performed, Jan. 15 and March 22, 1918. On evacuation, April 2, 1918 (Fig. 28), there was fibrous union in the right bicuspid region and mobility in the left second molar region.

All operations on the soft tissues, or for cleaning the mouth, except in Case 6, were performed under a local anesthetic.

SCHISTOSOMIASIS (OF BILHARZ) ASSOCIATED WITH UNCINARIASIS

REPORT OF A CASE *

JAMES J. SHORT, M.D.
NEW YORK

The disease caused by *Schistosomum hematobium* of Bilharz, so rare in this country as to be of little importance to the general profession or even to the sanitarian, may, nevertheless, because of its infrequency, prove of sufficient interest to warrant the publication of an account of a case. A brief description of the disease may also be of interest.

Although seldom seen here, this disease is so prevalent in Egypt, it is said, that fully 50 per cent. of the population is affected. In this country only a few cases have been reported, and all cases seen thus far have been imported.

The schistosomum belongs to the class of animal parasites known as the trematode, fluke or flatworm, and there are three distinct varieties pathogenic to man recognized by modern authorities: *Schistosomum hematobium*, *Schistosomum mansoni* and *Schistosomum japonicum*. Of the many names that have been attached to the particular variety here described, the term *Bilharzia hematobia* is perhaps the best known. In schistosomiasis the parasite itself occurs in the liver, and in the veins of the portal and urinary systems principally, particularly the mesenteric and vesical, depending on which variety of parasite is present.

The *Schistosomum hematobium* is bisexual and is commonly found united in pairs. The male is from 11 to 15 mm. in length and 1 mm. in breadth,[1] and has the appearance of a roundworm, this appearance being caused by the infolding of the flat body of the parasite to form a ventral, longitudinal groove, the so-called gynecophoric canal, which extends nearly its entire length, and serves for lodgment of the slender filiform female, the body of the male being actually wrapped around that of the female. On its ventral surface anteriorly are two suckers, and its body is thickly studded with small elevations. The female is longer, much more slender, darker in color, filiform and smooth. Its body is free at the ends, but is embraced in the middle by that of the male.

The ova are large and distinctive in appearance, being especially characterized by the presence of a very definite sharp spine on one end, and a capsule of varying thickness. Figure 1 presents their characteristic appearance. They are very readily detected by the low power of the microscope. For many years ova which were supposed to be those of *Schistosomum hematobium* have been observed which, instead of having a terminal, possessed a lateral spine. Numerous theories and conjectures were advanced to explain this condition, many investigators believing that the position of the egg in the tissues determined the location of the spine, others that the position of the spine denoted whether or not fertilization had taken place, and still others, that the two types of eggs belonged to different species. The latter view has recently been conclusively proved to be correct,[2] and it is now known that *Schistosomum hematobium* produces terminal-spined eggs only and *Schistosomum mansoni* lateral-spined eggs, while those of the *Schistosomum japonicum* are spineless. In general it may be stated that the first mentioned variety causes urinary disease, the second rectal disease, and the third disease of the colon, rectum and mesenteric nodes.

---

* From the Department of Laboratories, New York Post-Graduate Medical School and Hospital.

[1] Manson, Sir Patrick: Tropical Diseases, Ed. 6, New York, Cassell & Co., 1917, p. 743.

Until recently nothing was known of the life of this interesting parasite outside the human host, or of the manner in which it gained entrance to the body. Now it is known that the ovum, containing a living larva, leaves the body in the urine, and after coming in contact with fresh water, ruptures the enveloping capsule and escapes, swimming about actively by means of numerous ciliary projections. Later the larva, or miracidium, finds an intermediate host in the body of a certain snail—*Bulinus*—in the case of *Schistosomum hematobium*. In the liver of the snail it develops into great numbers of long cylindric bodies, the sporocysts and daughter sporocysts. Within each of these a cercaria develops and escapes into the water. This has the power of penetrating the skin of man and other animals, and so gains entrance to the blood vessels and lymphatics. By this route it finally reaches the liver, where it is ready to begin a new cycle of development into the flatworm.

Fig. 1.—Characteristic appearance of (*A*) ovum of Schistosomum hematobium; (*B*) miracidium; (*C*) ruptured capsule; (*D*) ovum of uncinaria. (This and the accompanying illustration were drawn by K. K. Bosse.)

After about six weeks the worms reach maturity, unite in pairs and descend, against the current of blood, into the mesenteric and vesical veins, the bilharzian variety choosing the latter route, thus gaining entrance to the bladder wall, where the eggs are deposited. Just how all this is accomplished is still somewhat obscure, but it seems natural to suppose that the suckers of the male play an important part, as they do in other animal parasites. The eggs being deposited in the bladder wall, the life cycle of the parasite is completed, and in the majority of cases symptoms are produced.

The symptoms of the disease vary somewhat in different persons depending on the severity of the infection, the condition of the person, his occupation, etc. The most constant symptom is a terminal hematuria caused by the passage of the ova through the bladder wall, this passage in all probability being effected by means of the sharp terminal spinous process. Having fallen into the bladder, the ova are voided in the urine, especially in the last few drops excreted, which contain the greatest amount of blood. Pain is frequently present in the region of the bladder and along the urethra. Complications may arise from the cystitis, such as renal calculus, urinary retention, hydronephrosis or pyonephrosis, pyelitis, etc., which may cause serious consequences and even death; these give the usual symptoms of those conditions. Anemia also may result, causing constitutional predisposition to other diseases. Other complications which are said not to be uncommon are urinary fistula and urethral stricture.

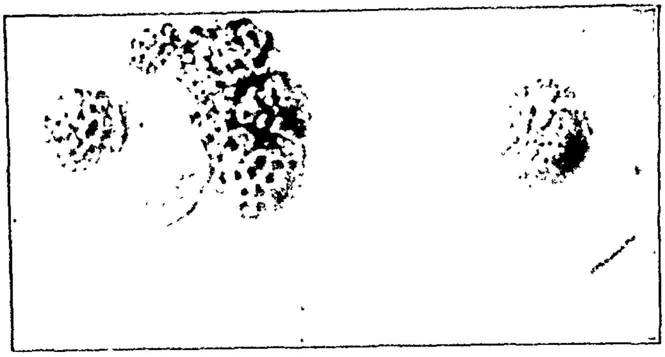

Fig. 2.—Cystoscopic view (reproduced through the courtesy of Dr. J. Bentley Squier, director of the Department of Urology).

The pathology of this disease may vary from a mild cystitis with dilated vessels, catarrhal mucous membrane, slight hemorrhage, and small vesicular or papular elevations, to a condition with marked thickening of the bladder wall, destruction of the mucosa, excrescences or new growths projecting into the bladder, encroaching on its capacity, etc. The trigon is said to be the portion most frequently affected, and thickening of this may easily cause occlusion of one or both of the ureters. There is a tendency to the formation of polypoid growths within the bladder, and these are often markedly pedunculated. The small elevations of the mucosa contain ova in large numbers; they occur chiefly in the submucous layer, and their presence tends to produce connective tissue formation, as is the case with any foreign body. The new growths are said occasionally to undergo malignant change, so that the disease must be regarded as causing a predisposition to malignancy. Other organs may also become invaded, notably the seminal vesicles, vagina, uterus and rectum; but this is rather unusual. In very exceptional instances even the viscera of the thorax have been involved.

Diagnosis is readily made by finding the ova in the urine. Examination with the cystoscope may yield valuable information as to the severity of the infection, and the extent of the damage wrought.

[2] Leiper, R. T.: Relation Between Terminal-Spined and Lateral-Spined Eggs of Bilharzia, Brit. M. J. 1: 411 (March 18) 1916.

The prognosis, according to all writers on the subject, is that of a very chronic cystitis, which is not fatal per se, but may become so through some complication. The smaller the number of worms present, the better the outlook, for obviously these cannot multiply within the human host. Those already present, however, may live for many years and continue to cause symptoms. Removal of the patient from the district in which the disease prevails will prevent reinfection and offer a better chance for eventual riddance of the worms.

Treatment must necessarily be essentially symptomatic, the chief object being to prevent some serious complication. It would appear that nothing could be administered to kill the parasite within the blood vessels without harm to the patient, although good results have recently been reported by the use of emetin intravenously.[3] The general condition of the patient must be looked after, new growths removed, fistulas repaired, ulcerations remedied so far as possible, etc. In the medical treatment many remedies have been tried, but without much success. The hope is that the parent worms may finally die, and thus the extrusion of the ova cease.

Prevention can be effected by avoiding contact with water in endemic districts that has not been rendered free from cercariae by boiling or by some chemical agent. These are able to live only forty-eight hours after being discharged from the snail, but a snail may remain infective over a long period and continue to give off cercariae.[1] Preventing excreta from coming in contact with fresh water would also be effectual, but this, of course, is a hard matter to control. It is said[1] that the cercariae are able to pass through the ordinary municipal filter bed without difficulty, but are easily killed by most of the ordinary germicides used in water purification.

In the foregoing introduction an attempt has been made to outline as briefly as possible what is known regarding the *Schistosomum hematobium* and the disease which it causes. For more extensive information concerning this and the other two types of schistosomiasis, reference is made to the more exhaustive treatises on the subject.

REPORT OF CASE

History.—M. G., a Russian Jew, aged 31, single, presented himself to the Advisory Board situated in the building of the New York Post-Graduate Medical School and Hospital in October, 1918 for examination. He had been born in Russia near Moscow, and had left Russia in 1914 for Palestine, where he remained about a year, leaving there for Egypt early in 1915. He remained in Egypt near Cairo for about a year, during which time he was engaged in farm labor, principally at digging irrigation ditches. He worked barefooted, often standing in water up to his knees or waist. After he had been engaged in this work for about one month he noticed that his urine was no longer clear, and that he had hematuria. He was warned to leave the country at this time, but remained eleven months longer, and then left for America.

Since first observing the blood he had a marked terminal hematuria which he thought had neither abated nor become more intense, although he had observed that the early morning urine contained less blood than at other times during the day. Subjectively, since the beginning, he suffered a slight pain and burning sensation along the urethra, especially near the external meatus, that would last for about five minutes after each micturition. At the onset he was also troubled with great frequency, having to urinate about every half hour; the latter symptom had greatly abated so that he now had a binocturia with only slightly or no increased frequency during the day. He also stated that during the time he remained in Egypt he lost about 25 pounds in weight, which he had not been able to regain; that his general health had not been so good as formerly; that he now became tired very easily, and that all sexual desire was lost. His present occupation was that of shipping clerk in a laundry.

Examination.—The man was sent by the Advisory Board to the laboratory for urinary examination. Observation disclosed that about 5 c.c. of what appeared to be pure blood were passed at the end of urination, and microscopic examination confirmed the presence of a large amount of blood besides large numbers of the ova of the *Schistsomum hematobium* of Bilharz. These were very typical in appearance, having a terminal spine, and it is interesting to note, from a biologic standpoint, that in a large number of examinations, during which hundreds of ova were seen, not one with a lateral or subterminal spine was found.

An attempt was made to rupture the enveloping capsule and set the miracidium free by diluting the urine with fresh water. This proved successful, one ovum being observed during the process. The rupture was sudden and complete. Figure 1 shows the ovum and miracidium as they appeared with a Leitz ocular No. 4, objective No. 6.

A blood examination was next made, which revealed: hemoglobin (by Sahli method) 100 per cent.; erythrocytes, 4,344,000; color index, 1.16; leukocytes, 8,400; differential count of leukocytes: neutrophils, 56 per cent.; lymphocytes, 43 per cent.; basophils, 1 per cent. Contrary to expectations, no eosinophils were found in this examination even after prolonged search. Subsequent examinations, however, revealed an eosinophilia ranging around 6 and 7 per cent. No change of any significance was seen in the other elements.

Chemical examination revealed: urea nitrogen, 17.2, uric acid 2.5, and creatinin 2.3 mg. per hundred c.c. of blood, which would indicate that the kidneys either were not involved, or were at least still able to carry on normal functional activity. The blood sugar was 0.13 per cent.

The Wassermann test was negative.

The patient was admitted to the hospital for observation and treatment, October 22, and a cystoscopic examination was then made by Dr. Maximilian Stern, and later a second examination was made by Dr. J. F. McCarthy. Dr. Stern reported that the trigon and ureteral orifices were pale and apparently normal; the right lateral wall had several herpetic areas consisting of yellowish white, pinhead sized spots in clusters, surrounded by a red areola; in some of these areas the white elevations were nearly spherical, as if ready to erupt. On the posterior aspect of the bladder mucosa were seen carcinomatous-like elevations, ragged and red, one of which was pedunculated and spherical, of about the size of a hazelnut. Several of these masses were present in herpes-like patches.

The physical examination was negative, revealing a man well nourished and apparently normal. The liver was normal in size, shape and consistency, so far as could be ascertained.

Since *Schistosomum hematobium* is said occasionally to invade other organs of the abdomen and pelvis besides the bladder, an examination of the feces was made for evidence of intestinal involvement. The benzidin test for occult blood was very strongly positive, and careful search with the microscope showed a complete absence of eggs of the schistosomum. Hookworm eggs, however, were present in quite large numbers. It seems most probable to suppose that the latter disease was also contracted during the patient's stay in Egypt. In several instances living hookworm embryos were observed within the egg capsules, and incubation for twenty-four hours caused a rupture of the capsule and emergence of the embryo, so that after incubation the living embryos could easily be found in the stool.

Treatment and Result.—Treatment of the case consisted chiefly of bladder irrigations with argyrol and silver nitrate. Hematuria was lessened and the patient was dicharged, October 31, the general condition being considerably improved.

THE COMPLEMENT FIXATION TEST IN INFLUENZAL PNEUMONIA

STUDIES WITH SERUM FROM CONVALESCENT PATIENTS, THE INFLUENZA BACILLUS BEING USED AS ANTIGEN *

F. H. RAPOPORT, M.D. (New Haven, Conn.)
Lieutenant (Junior Grade) M. C., U. S. N. R. F.
CHELSEA, MASS.

These experiments were performed to ascertain whether patients who had recovered from the bronchopneumonia accompanying influenza had developed antibodies that could be demonstrated by the complement fixation test, *Bacillus influenzae* being used as antigen.

During the recent epidemic in the First Naval District, attempts were made in this laboratory to demonstrate agglutinins, precipitins or opsonins in the blood of the patients who had the disease. The results so far have been negative with *B. influenzae*. This, indeed, was disappointing, as it was hoped that individuals who had recovered might show some demonstrable changes in the blood which would indicate the part the immune processes might have played in their recovery.

This expectation was especially strengthened in view of the highly suggestive results obtained by Drs. McGuire and Redden[1] in their treatment of patients in the active stage of influenzal pneumonia with serum from patients who had recovered from the condition. Hartman,[2] and Ross and Hund[3] have described the use of citrated blood in treating similar cases, and they also report favorable results.

At first, the serums from patients having uncomplicated influenza were tested, but these did not give very satisfactory or encouraging results. Consequently, the serums from patients who had had influenzal pneumonia were studied.

The object of this series of experiments has been to throw light on these questions:

1. Does the influenza bacillus (found in more than 80 per cent. of the lungs at necropsy in this laboratory[4]) give rise to the formation of specific antibodies?
2. Is the complement fixation test of any value in confirming a diagnosis of the bronchopneumonia accompanying influenza?
3. Can one demonstrate the complement-fixing antibodies in the serums of recovered individuals, which serums have been found valuable in the serotherapy of influenzal pneumonia?
4. Did many strains or only one specific strain of *B. influenzae* become virulent during the epidemic?

ANTIGENS

Preparation.—Antigens were prepared by various methods, and their respective values were determined by titration. The methods are described in the order of antigenic superiority of different preparations:

Method 1: The influenza bacillus was obtained at necropsy from the lung, being grown on blood agar plates. Characteristic colonies were transferred to flasks containing 100 c.c. of glucose broth (0.5 per cent.) and 5 drops of sheep's blood previously diluted with broth 200 times (by volume). After three days a good growth usually was obtained. To control the purity of this culture, a loopful of it was streaked out on blood agar, and twenty-four hours later the plate was examined. If this test was satisfactory, 0.3 per cent. tricresol was added to the glucose broth culture and it was again incubated at 37 C. for twenty-four hours, when it was tested for sterility. The killed broth culture was centrifuged for twenty minutes at 2,500 revolutions per minute. The supernatant fluid was poured off and the sediment taken up in 40 c.c. of physiologic sodium chlorid solution and washed three times by centrifuging with fresh salt solution (0.85 per cent.) each time. Finally, the washed sediment was taken up in exactly 30 c.c. of saline (0.85 per cent.). Sterile beads were added and the suspension shaken for twenty minutes.

Fourteen different antigens were made in this manner, each one being prepared from a culture of influenza bacillus obtained from a different necropsy. Of this number only nine were found to possess good antigenic value.

Method 2: Five antigens made from a mixture of more than one strain of influenza bacillus were prepared, in the same way as described in Method 1. Three of these five antigens contained four different strains of the influenza bacillus; one contained six strains, while one had eight strains.

Method 3: These antigens were made as in Method 1, except that after the sediments had been washed, the bacteria were ground up in a sterile mortar and then 30 c.c. of physiologic sodium chlorid solution were added.

Method 4: Sections of lung tissue weighing 2 gm. were selected from patients that had died from influenzal bronchopneumonia. These portions of tissue were examined, and when they showed a gram-negative bacillus, morphologically and culturally resembling the Pfeiffer bacillus, 0.3 per cent. tricresol was added and the tissue was ground up in a sterile mortar. Twenty-four hours later, after incubation at 37 C., it was tested for sterility. The final volume was made up to 30 c.c. by the addition of salt solution.

Method 5: The influenza bacillus was grown as described in Method 1. The broth culture was centrifuged for twenty minutes at 2,500 revolutions per minute. The sediment was washed three times with salt solution, and the sediment was then taken up in 30 c.c. of salt solution (0.85 per cent.). This suspension was then heated for one-half hour at 56 C. It was then tested for sterility by streaking a loopful on blood-agar and incubating for twenty-four hours at 37 C. When no growth was evident after twenty-four hours, 0.1 c.c. of 1 per cent. phenol to every cubic centimeter of antigen was added as a preservative.

Method 6: A gram-negative bacillus resembling Pfeiffer's organism, by culture and morphology, was obtained from the bronchial sputum of two patients having influenzal pneumonia. (These patients subsequently recovered from the disease.) The preparation of the antigen was the same as in Method 1.

Method 7: The influenza bacillus was grown on blood agar. A staphylococcus was planted on the plate to cause a more abundant growth. After twenty-four hours, an attempt was made to wash off the influenza colonies; but a staphylococcus contamination could not be avoided by this method. Tricresol, 0.3 per cent., was added, and the final volume was made to 30 c.c. by the addition of physiologic sodium chlorid solution. After twenty-four hours' incubation, the antigen was tested for sterility.

Conclusions from a Comparative Study of These Antigens.—1. The preparations described in Method 1 form the best antigen.

---

* Owing to lack of space, this article is abbreviated in THE JOURNAL by the omission of a table giving the results of the tests in detail. The article appears in full in the reprints, a copy of which may be obtained on application to the author.

2. Grinding up the antigen gave only about 20 per cent. as many positive results as those obtained from the antigen of Method 1.

3. The polyvalent antigens were of no higher antigenic value than those made from a single strain.

4. Antigens made from bacteria grown on solid mediums (Method 7) were not satisfactory, since the suspensions contained too much blood and it was difficult to obtain a suspension that did not also contain the staphylococcus. The antigenic value was very low.

5. The antigens obtained from the organism that was found in the bronchial sputum was valueless.

6. Heating apparently destroys, in a large measure, the complement-fixing substance of a bacterial antigen.[5]

7. The organism obtained from the early cases in the epidemic supplied a better antigen for the fixation test than those from the late cases.

8. The antigens do not deteriorate very rapidly. Some of them retained their power to fix complement three months.

TITRATIONS

The anticomplementary and hemolytic values of each antigen were determined by titration. In finding the anticomplementary dose, varying amounts of the antigen, 0.02, 0.05, 0.1, 0.3, 0.5, 0.7, 0.8, 1.3, 1.5 and 2 c.c. of the undiluted antigen, were added to a series of tubes. To each tube, 1 c.c. of 1:20 complement was added. The volume of each tube was made to 3 c.c. with physiologic sodium chlorid solution. The tubes were then incubated for one and one-half hours at 37 C. Then 0.5 c.c. of amboceptor containing 2 units and 0.5 c.c. of a 2.5 per cent. suspension of sheep's corpuscles were added. The tubes were reincubated for three-quarters hour, when a reading was made. That tube which first showed inhibition of hemolysis contained the anticomplementary unit of antigen.

Of all the antigens made, only three were found to be anticomplementary. In these instances, the antigenic unit was one quarter of the anticomplementary unit. The many antigens that were not found to be anticomplementary were used undiluted. It was found that usually 0.2 c.c. of the undiluted antigen was the antigenic unit when a definite volume of glucose broth (100 c.c.) was used and when the final volume was made to 30 c.c. with salt solution, as described in Method 1.

Each antigen was then titrated against six known positive and six known negative serums before it was used in a series of experiments.

When the antigenic unit was found, this amount of antigen was mixed with 0.5 c.c. of a 2.5 per cent. suspension of sheep's corpuscles, and these were incubated for one-half hour at 37 C. This procedure determined whether the antigen was at all hemolytic in the amount representing one unit.

When the foregoing factors were definitely controlled, the antigen could be used in the tests.

Only a brief description of the reagents used is necessary, since the methods of preparation are practically the same as in the Wassermann reaction:

Complement.—Pooled serum of guinea-pig's blood was used. One hour after the blood was obtained, it was centrifuged and the serum was diluted 1:10 with physiologic sodium chlorid solution. In preparing the complement for titration, 10 c.c. of physiologic sodium chlorid solution were added to 10 c.c. of the 10 per cent. guinea-pig serum.

Serum.—The serums were inactivated for twenty minutes at 56 C. It was found that heating had also a tendency toward destroying antibodies.

Amboceptor.—The hemolytic amboceptor was the same as that used in this laboratory in doing the Wassermann tests. Briefly, it was obtained by immunizing rabbits with sheep's corpuscles. Two units of amboceptor were used in the fixation tests. The amboceptor was diluted so that 0.5 c.c. contained two units.

Sheep's Cells.—These were obtained by a puncture of the jugular vein of the sheep under sterile precautions. The blood was defibrinated with sterile beads, and then 10 c.c. of the blood were put in a 40 c.c. graduated tube. Physiologic sodium chlorid solution was added to 35 c.c. This corpuscle suspension was centrifuged for fifteen minutes at 2,500 revolutions per minute. These corpuscles were washed three times in this way. After the final washing, the supernatant fluid was poured off and the packed cells were read. A 2.5 per cent. suspension of these washed sheep's cells was made by diluting with physiologic sodium chlorid solution.

Sensitized Corpuscles.—Sensitized corpuscles consist of equal parts of 2.5 per cent. suspension of sheep's corpuscles and diluted amboceptor. This mixture was incubated for one-half hour at 37 C. One c.c. of this mixture was used in the complement fixation test.

Before each series of tests, a preliminary combined titration of complement and amboceptor was made, as shown in Table 1.

TABLE 1.—PRELIMINARY COMBINED TITRATION OF COMPLEMENT AND AMBOCEPTOR

Tube	Complement 1:20 Dilution C.c.	Amboceptor 2 Units in 0.5 c.c. C.c.	Sheep's Cells 2.5% Suspension C.c.
1	0.5	0.5	0.5
2	0.4	0.5	0.5
3	0.3	0.5	0.5
4	0.2	0.5	0.5
5	1.0	0.3	0.5
6	1.0	0.2	0.5

To each one of the six tubes in Table 1, physiologic sodium chlorid solution was added to make a volume of 3 c.c. The tubes were incubated at 37 C. for one-half hour. In reading, the least amount of guinea-pig serum causing complete hemolysis determined the size of the unit of complement. If the amboceptor was satisfactory, Tube 5 showed complete hemolysis, while Tube 6 showed moderate hemolysis.

After the combined titration of the complement and amboceptor had been completed, the complement fixation test was thus performed:

Two rows of tubes were set up, as indicated in Table 2. One-tenth c.c. of each of the serums was flowed into one of the tubes in each of the two rows. To each tube in the front row 0.2 c.c. of the antigen and one unit of complement were added. To the rear tubes only one unit of complement was added. The volume of every tube was made to 2 c.c. by the addition of physiologic sodium chlorid solution. Therefore, the front row for each test contained one unit of complement, 0.2 c.c. of antigen and 0.1 c.c. of serum and salt solution, while the respective rear tube contained all of these except the antigen.

These additional controls were made with every series of tests:

(*a*) Antigen control, containing the unit of complement, the unit of antigen, and physiologic sodium chlorid solution to 2 c.c.

(*b*) Hemolytic control, containing the unit of complement and physiologic sodium chlorid solution to 2 c.c.

All the tubes were then shaken thoroughly and incubated for one and one-half hours at 37 C. Then 1 c.c.

---

[5] Perry, M. W., and Kolmer, J. A.: A Study of the Immunizing Properties of Bacterial Vaccines Prepared after Various Methods, J. Immunol. 3: 258 (July) 1918.

of sensitized corpuscles was added to each tube and they were reincubated for three quarters of an hour, when a preliminary reading was made. The tubes were put into the refrigerator, and a final reading was made the next morning.

As mentioned above, these tubes were incubated at 37 C. for one and one half hours, when 1 c.c. of sensitized corpuscles was added. The tubes were reincubated then for three quarters of an hour and a preliminary reading was made. There should be complete hemolysis in Tubes II, III and IV. If the serum is anticomplementary, there will be inhibition of hemolysis in Tube II, and no reading can be made in Tube I. But if this is not so and there is inhibition of hemolysis in Tube I, then this serum is positive, while it is negative when there is hemolysis.

PERFORMANCE OF THE EXPERIMENTS

As mentioned previously, this series of experiments was performed to determine the occurrence of the complement fixation test on serums from patients who were recovering from influenzal pneumonia, the condition having been determined by physical and clinical signs. To control the specificity of the reaction, a number of individuals were examined who gave no history of the disease during the epidemic and who stated that they were not subject to colds and coughs. Some stress was laid on the last factor, since an ambulatory form of influenza is very probable.

TABLE 2.—SCHEME FOR THE COMPLEMENT FIXATION TEST

Tube II Unknown Serum 0.1 c.c. of serum (Patient A) 1 unit of complement Physiologic sodium chlorid solution added to 2 c.c.	Tube IV Antigen Control 0.2 c.c. of antigen 1 unit of complement Physiologic sodium chlorid solution added to 2 c.c.
Tube I 0.1 c.c. of serum (Patient A) 1 unit of complement 1 unit of antigen (0.2 c.c.) Physiologic sodium chlorid solution to 2 c.c.	Tube III Hemolytic Control 1 unit of complement Physiologic sodium chlorid solution to 2 c.c.

It may be questioned whether such serums could be used as satisfactory controls, as it may be that those that did not come down with the disease had enough antibodies or natural immunity to overcome the virulent organism. This may explain the positive results obtained from some of the controls.

A few serums were tested from patients who still had a high temperature due to the pneumonia, and these are also included in Table 3.

It was endeavored to test blood from patients at different periods of convalescence. Some serums were tested when the temperature had been normal one day, while others were tested when the patients had been convalescent for forty-one days.

When serums were found to be positive, they were later tested at different intervals so as to determine how long the antibodies persisted.

The test and control serums were all negative to the Wassermann reaction, which was performed simultaneously.

MAIN RESULTS FROM THE TESTS

1. Of the 300 control serums tested, twenty-nine, or 9.6 per cent., reacted positively.

2. Of the 315 serums from patients convalescing from influenzal pneumonia, the complement fixation reaction showed 161 positive reactions, 134 negative and twenty anticomplementary reactions. In other words, excluding the anticomplementary serums, 54.5 per cent. of convalescent influenzal pneumonia serums were positive.

3. Of the 161 positive serums, twenty (12.42 per cent.) were +, thirty-four (21.12 per cent.) were ++, forty-five (27.95 per cent.) were +++, and sixty-two (38.51 per cent) were ++++.

4. Some of the serums were positive one day after the patient had become convalescent. Other serums from patients convalescent forty-one days were positive. Most of the positive reactions were obtained with serums from individuals who were convalescent from three to five days.

5. Some serums that reacted positively three months ago still can fix complements.

TABLE 3.—TESTS IN WHICH WHITE BLOOD COUNTS WERE MADE

* In this column + indicates hemolysis between 75 and 100 per cent.; ++, hemolysis between 50 and 75 per cent.; +++, hemolysis between 25 and 50 per cent.; Neg., complete hemolysis.

6. The fixation test on many serums made during the time that the patient was still acutely ill or just beginning convalescence were in many cases negative or slightly positive; but when these serums were kept in the refrigerator for from six days to three weeks, many gave strongly positive reactions.

7. White blood counts were not made on all influenzal pneumonia patients admitted, but of those patients on whom one was made and whose serums were tested by the complement fixation test, Table 3 has been made. This table shows that of the forty-nine patients who had a white count above 10,000, thirty (61.28 per cent.) gave a positive reaction; while of

the same number having a white count below 10,000 per cubic millimeter, only fifteen (30.61 per cent) produced a positive complement fixation test.

COMMENT

The complement binding factor of serum from influenzal pneumonia patients is probably a very weak one. At first, when two units of complement were used, many more negative results were obtained than when one unit was finally resorted to. Two units probably produced a marked excess of complement for that factor of the serum that causes complement fixation.

The results suggest strongly that the influenza bacillus forms specific antibodies that will fix complement when this organism is used as an antigen.

It is difficult to conclude definitely from these experiments alone whether only one or many strains of the influenza bacillus were active during the epidemic; but this can be stated: Polyvalent antigens did not give more positive results than a monovalent one. If many strains of this organism were present, then one could have expected more positive reactions in these experiments than were obtained from the use of an antigen made from one strain.

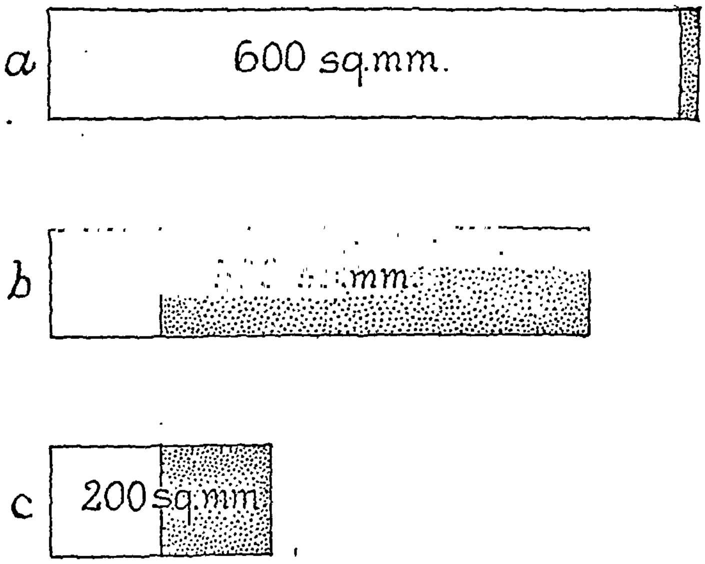

Fig. 1.—Relative importance of eye exposure to direct droplet spray: *a*, average total eye surface exposed; shaded area represents proportion of time not exposed, due to winking; *b*, average total mouth area exposed in talking; shaded area represents proportion of time not exposed, due to closure; *c*, average total area of cross-section of nares exposed; shaded area represents proportion of time not exposed, owing to protected position and expiration.

Serums that gave positive tests were also found more suitable for the serotherapy of influenzal pneumonia patients. It seems possible that persons who have *not* had influenzal pneumonia, but whose serum gives a positive reaction, might be useful as donors.

Since some of the reactions were inconstant, it must be concluded that the complement fixation test in influenzal pneumonia cannot yet be accepted as a diagnostic test; but it may be of some value together with other diagnostic methods in confirming the condition as having been present, at least in more than 50 per cent. of the cases.

This presence of complement fixation would indicate that the influenza bacillus plays an important part in the complicating pneumonia of influenza; but the results furnish no conclusive evidence of a primary etiologic rôle of the influenza bacillus.

SUMMARY

Experiments were made for the purpose of determining whether specific antibodies existed in the serum of patients who were convalescing from influenzal pneumonia.

The influenza bacillus found in more than 80 per cent. of the necropsies at this laboratory was used as an antigen.

The presence of antibodies was demonstrated by the complement fixation test, for it was found that out of the 300 control serums 9.6 per cent. gave a positive reaction, while of the 295 serums from convalescent influenzal pneumonia patients, 54.5 per cent. had antibodies that fixed complement.

THE TRANSMISSION OF INFECTION THROUGH THE EYE

KENNETH F. MAXCY, M.D.
Captain, M. C., U. S. Army
FORT SILL, OKLA.

Recently the eye has received little or no attention as a factor in the transmission of acute respiratory infections. It has been disregarded in planning measures for the prevention of the spread of contagious diseases. This was especially true in the recent epidemic of influenza. No provision has been made in the ward routine of contagious hospitals for the protection of the eye of healthy persons in attendance on the unmasked sick. A brief consideration of the anatomic relations and physiologic facts of the lacrimatory-nasal mechanism, together with certain simple experiments illustrating its modus operandi, will convince one of the reality and importance of this portal of entry for pathogenic micro-organisms.

It has long been known that large numbers of various organisms, including the pneumococcus, streptococcus, influenza bacillus, and many others, may be recovered from the conjunctival sac, especially if there is obstruction to the overflow of tears. The conjunctival sac is never sterile. The source of contamination has been attributed largely to the impingement on the conjunctiva of the eyeball and the cornea of dust particles bearing micro-organisms. It is evident that droplets sprayed from the mouths of other persons during the act of talking, laughing, coughing, sneezing, etc., must be another frequent source.

It is now generally accepted that many contagious diseases are transmitted from one person to another through this direct droplet spray. Experimentally it has been shown by Doust and Lyon[1] that a person infected with a micro-organism (*B. prodigiosus*) may project this organism from his mouth during ordinary conversation or loud speech to a distance of 4 feet, and that during coughing, infected material from the mouth might be projected at least 10 feet. These observers, together with Haller and Colwell,[2] proved that this promiscuous spraying of the environment by an infected person could be entirely prevented by the wearing of a properly constructed gauze face mask. There is no experimental proof, however, that the reverse relation holds true, that is, that the noninfected healthy person is entirely protected from droplet spray by the wearing of such a mask. Droplets may not enter the nose or mouth when a face mask is worn, but the conjunctiva remains openly exposed. The relative importance of this portal of entry will become more evident if the conditions under which infection occurs are closely examined.

THEORETICAL CONSIDERATIONS

Infections are most likely to be transmitted during the waking hours when a person has his widest range of activity and is coming into intimate association with numbers of other human beings. This is especially true in crowds, in which the range for droplet spray is short. Under these conditions the mouth is closed a large part of the time, in particular when another (perhaps infected) person is talking to (spraying) the noninfected healthy person who assumes the attitude of a listener. With the mouth closed, only the lips may receive the droplets; the bacteria dry there and perish, or perhaps they are swept into the mouth by movements of the tongue. Furthermore, when a healthy person is talking, air currents are created that are adverse to the entrance of droplets from the infected. The mouth surface exposed to droplet spray may consequently be represented as averaging about 100 sq. mm.

The nares at such times may not be directly exposed, owing to the protected anatomic position when the head is slightly inclined forward. With every expiration, adverse air currents are created. Hence, although a cross-section of the nares gives an area of about 200 sq. mm., this is available for direct droplet spray less than half of the time.

Contrasted to these areas, some 600 sq. mm. of eye surface area is constantly exposed to droplet spray during the waking hours, except for the very brief intervals during the act of winking, an act which is in itself of significance for the mechanism, as will be seen later. Certainly the chances of infecting the eye are fully as good as those of infecting the nose and mouth, if not better. These relations are brought out graphically in Figure 1.

THE LACRIMATORY-NASAL MECHANISM

The disposition of organisms reaching the conjunctival sac through droplet spray or dust particles may be easily demonstrated by the use of some harmless saprophyte, preferably a pigment producer, such as *B. prodigiosus*. This will be made clear by the subjoined experiments and Figure 2.

By the winking movement of the lids, the surface of the eye is swept at regular intervals, and the lacrimal secretion, which has no bactericidal action, together with the contained micro-organisms, is carried into the nose through the lacrimal duct (Fig. 2, 1).

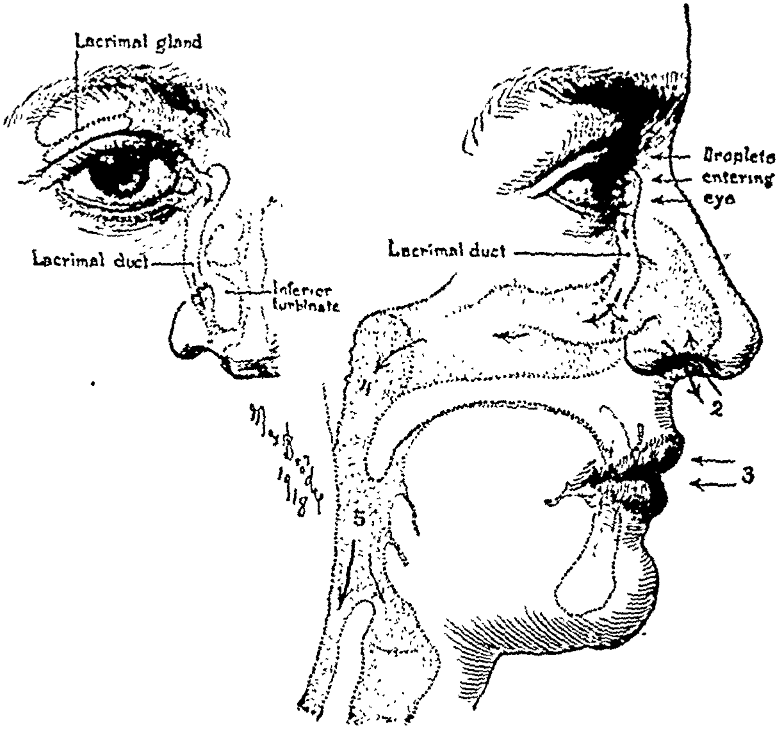

Fig. 2.—The lacrimatory-nasal mechanism for the mechanical disposition of organisms entering the upper respiratory tract.

EXPERIMENTS

EXPERIMENT 1.—*To show the appearance of organisms in the nose after introduction into the conjunctival sac.*

With a capillary pipet, 1 drop of suspension[3] was instilled into the eye near the inner canthus in each of five subjects. Just previous to the instillation, a straight swab was introduced into the nostril on the same side and smeared on the first quarter of an agar plate to demonstrate the absence of *B. prodigiosus* from the nasal fossa at the beginning of the experiment. In a similar manner a swab was introduced on *the same side at five, ten and fifteen minute intervals after* the instillation, and then smeared on agar plates. The plates were examined at twenty-four and forty-eight hours for colonies with characteristic pigmentation. The result of such an experiment is shown in Table 1.

It is evident from this experiment that *B. prodigiosus* instilled into the conjunctival sac is quickly carried into the nose, and that the organisms may there be recovered on a nasal swab within five minutes of the instillation. From the opening of the lacrimal duct (Fig. 2, 1) two courses are open. They may pass out through the anterior nares. This occurs when there is excessive secretion, or when the nose is "blown." Secondly, they may be carried backward into the nasopharynx (Fig. 2, 4). The topography of the nose favors the latter disposition, and this normally occurs in the absence of the factors mentioned above.

EXPERIMENT 2.—*To show appearance of organisms in the nasopharynx after introduction into the conjunctival sac.*

The details of the technic are the same as in Experiment 1. In addition, at the end of thirty minutes a long wire swab, slightly bent at the end, was introduced into the nasopharynx through the mouth and smeared on the agar plates. The result is shown in Table 2.

EXPERIMENT 3.—*To show appearance of organisms in the nasopharynx after introduction of diminishing doses into the conjunctival sac.*

The details of the technic are the same as in Experiment 2. In addition, the standard suspension used on the first subject was diluted 1:100 in the second, 1:1,000 in the third, and 1:10,000 in the fourth. A single drop from a capillary pipet was the dose instilled in each instance. The result is shown in Table 3.

Experiments 2 and 3 demonstrate that even very small doses of *B. prodigiosus* instilled into the conjunctival sac may be recovered from the nasopharynx from fifteen to thirty minutes later.

The disposition of organisms from this point (Fig. 2, 5) may follow one of three courses: 1. They may pass outward through the mouth with the sputum. 2. They may be carried into the larynx and reach the lower respiratory tract. 3. They may be carried downward into the esophagus with the swallowing movements, and perish in the intestinal canal or be excreted with the feces. The latter is probably the most frequent course.

---

[3] The standard suspension of B. prodigiosus used in these experiments was prepared by growing a 2 inch streak on an agar slant for from eighteen to twenty-four hours at incubator temperature, and washing the organisms off the surface with 2 c.c. of salt solution.

TABLE 1.—INSTILLATION OF B. PRODIGIOSUS INTO CONJUNCTIVAL SAC; RECOVERY FROM THE NOSE

		Result of Nasal Swabs				
No.	Subject	0 Min.	5 Min.	10 Min.	15 Min.	30 Min.

2	P.	0	0	0	—	+
3	B.	0	0	+	—	+
4	Br.	0	+	—	—	+
5	Pa.	0	+	+	+	+

Specimens of the stool were obtained from Subjects 7, 9 and 10, about twenty-four hours after they had submitted to Experiment 2. In one of the three (Subject 7), a viable *B. prodigiosus* was recovered. Success might have attended the other attempts had cultures been taken of successive passages.

The disposition outlined above holds true for the bulk of organisms introduced into the conjunctival sac. Larger or smaller numbers are left along the course, particularly on the nasal mucous membrane and in the adenoid tissue of the nasopharynx. If the biology of the organism is unsuited to the environment, its growth is inhibited or it is perhaps destroyed by neutralizing substances in the nose. If the biology of the organism is such that the environment is suitable for reproduction, growth ensues with resulting stimulation of protective mechanisms and manifestations of infection of the respiratory tract.

LIMITATIONS OF THE GAUZE FACE MASK

From the foregoing it is clear that the eyes present a relatively large surface for the reception of droplet spray, and that organisms introduced into the conjunctival sac quickly reach the nose and throat. It follows that the gauze face mask fails completely to close this portal of entry. This fact may be demonstrated experimentally:

Experiment 4.—*To demonstrate infection of the upper respiratory tract by droplet spray while a gauze face mask is being worn.*

The standard suspension of organisms was diluted 1:20 with salt solution so that it was slightly but definitely turbid. The suspension was placed in an atomizer connected with a compressed air tank. After a swab had been taken to show the absence of *B. prodigiosus* from the nose of the subject at the beginning of the experiment, the nose and mouth were covered with a gauze mask. All subjects, except 20 and 21, used a mask consisting of eight thicknesses of gauze, of 28 by 24 mesh. Subjects 20 and 21 used a three layer butter-cloth mask constructed according to the specifications of Doust and Lyon.[1] Besides wearing the mask, the first five subjects were instructed to hold their hands over their mouths, closing off the nostrils and holding the breath during exposure. The atomizer was directed toward the faces of the subjects from a distance of from 3 to 4 feet, and the spray applied twice—each application lasting about a second—imitating a couple of coughs. With the last four subjects, particular care was taken to exclude the possibility of organisms gaining entrance through inhalation. The swabbing was done in one room, and the exposure to spray in another. The subjects, having previously been masked, were brought into a room where they were exposed, and then immediately withdrew to the room where the swabs were taken. The mask was worn during the whole twenty minutes of observation except when the swabs were being taken.

The result is shown in Table 4.

The result is unequivocal. It may be repeated by any one for his own satisfaction. The possibility of infecting the upper respiratory tract through the eye by direct droplet spray, even when a properly constructed mask is worn, is an easily demonstrated fact.

COMMENT

The frequency with which respiratory infections—for example, acute coryza, measles and influenza—begin with a conjunctivitis suggests that this entrance for the causative organism may not be uncommon. It is realized that the conjunctivitis in certain cases is simply a suffusion and part of the general mucous membrane response. In other cases the priority and prominence of this symptom indicates rather a primary relationship with the disease. Certainly the evidence is sufficient to warrant serious consideration of this portal of entry in planning measures for the prevention of the spread of contagion. The obvious means of protection is the wearing of a large lens or pair of goggles in addition to the gauze mask by those who are within range of droplet spray from heavily infected individuals. In this connection it is interesting to note that during the great epidemics of plague that have from time to time swept over the Old World, masking of the whole face, eyes included, has been wonderfully effective.

The gauze mask is efficient in preventing the infected person from spraying his environment, and should be used for this purpose when possible. It is impracticable to mask very sick patients, especially those with respiratory difficulty. These patients are prolific distributors of droplet spray. Physicians and attendants, even though properly masked, cannot come within close range of such persons without the danger of infection through the eye. Public health administrators should bear in mind the limitations to the protective value of the gauze mask when worn by the noninfected. The pathologist at the necropsy table should remember that infectious material splashed into the eyes is just as potent as if it had been directly implanted on the mucous membrane of the nasopharynx.

CONCLUSIONS

1. The eyes offer a relatively large surface area for the reception of droplets sprayed from the mouths of other persons.
2. An organism introduced into the conjunctival sac may be recovered from the nose in five minutes, from the throat in fifteen minutes, and from the stool in twenty-four hours.
3. The upper respiratory tract of a person wearing a properly constructed mask may be infected by exposing the eye briefly to direct droplet spray.
4. This portal of entry is of importance in the transmission of acute respiratory infections.

HYSTERICAL APHONIA ASSOCIATED WITH LATENT SYPHILIS

REPORT OF CASE

CHARLES WOLF, M.D. (New York)
Captain, M. C., U. S. Army; Chief of Dermatology and Syphilis, Walter Reed General Hospital
AND
E. G. BREEDING, M.D. (Baltimore)
Captain, M. C., U. S. Army; Chief of Section of Otolaryngology
TAKOMA PARK, D. C.

A well developed man, aged 36, 5 feet 11 inches in height, whose habits were good, who drank beer occasionally, smoked moderately and was a telegrapher, enlisted in the Army, Jan. 10, 1918, at Fort Thomas, Ky. While on a furlough at home, he developed a cold and an eruption which a civilian physician diagnosed as measles. Hoarseness accompanied by a cough first appeared at this time and progressively increased until January 18, when the patient completely lost his voice. He was sent to Fort Wood, N. Y., for treatment. The post surgeon there referred him to the Manhattan Ear and Throat Hospital, where he received active treatment from February 20 to March 30. His condition apparently remained the same; several Wassermann tests had been negative, and no definite diagnosis could be made. The soldier was then transferred to the Canal Zone in the belief that a climatic change might affect the aphonia, and reported there for duty, April 15, where he was shortly afterward admitted to the Ancon Hospital.

July 6, a blood test gave a + + Wassermann reaction for the first time; July 11, the spinal fluid gave a negative Wassermann reaction; July 12, a blood test was again + +. With a history of a sore on the penis in 1906 and the presence of a scar there, together with a + + Wassermann reaction, it was decided to institute specific treatment. He therefore received five arsphenamin injections intravenously, six mercuric salicylate injections intramuscularly, and potassium iodid by mouth between July 23 and August 19. August 8 and 19, the Wassermann tests were reported negative with no improvement in the aphonia.

September 30, the patient was transferred to the Walter Reed General Hospital for final disposition. Two Wassermann tests were taken, one, October 2, and the other, October 7; the former was negative, the latter ±. A neurologic examination revealed slightly exaggerated knee jerks, a marked Romberg sign, but no Babinski reflex or ankle clonus. The laryngologic examination revealed no pathologic condition of the vocal cords; the tonsils were in a state of chronic hypertrophy; otherwise the patient was normal. In view of the foregoing symptoms, a lumbar puncture was performed. October 17; the spinal fluid was clear and under normal pressure. All the tests, namely, the Wassermann, globulin, colloidal gold and cell count, were negative. Although the biologic tests were normal, still we felt justified in administering further specific treatment in the expectation that the therapeutic test would throw further light in clearing up the diagnosis.

Accordingly the patient received four intravenous injections of arsphenamin, 0.5 gm. each, four injections of mercuric salicylate intramuscularly at weekly intervals, and potassium iodid by mouth, from October 22 to November 12. The Wassermann test, November 4, was still ± with no change in the patient's aphonia and the Romberg sign.

After much deliberation, it was decided to examine the larynx under ether anesthesia. December 12, the patient was anesthetized and the larynx examined by the direct method. Nothing abnormal was found to account for the aphonia; only a slight congestion of the false cords was noted. When reacting from the anesthetic, the patient began to speak in normal pitch and his voice remained so up to December 31, when it was decided to return him to duty. The Romberg sign was still present, which we believe to be purely functional. Before the administration of the anesthetic the patient was told that an operation would be performed in his throat, after which his voice would be restored. After the patient reacted, he complained of some soreness which he thought was due to the operation. The passage of the laryngoscope probably set up enough irritation to account for the complaint.

DIFFERENTIAL DIAGNOSIS

From the standpoint of differential diagnosis, the following conditions had to be considered:

1. *Acute and Chronic Laryngitis.*—This condition, with the symptoms starting as an acute laryngitis and going into a chronic condition, was thought not probable, as no improvement followed local treatment.

2. *Tuberculosis of the Larynx.*—This condition following an attack of measles had to be considered. The symptoms appeared suddenly, there was no pain, and there was an absence of laryngeal and pulmonary signs, all of which eliminated this diagnosis.

3. *New Growths.*—There was no local or constitutional evidence of these.

4. *Interstitial Neuritis of the Recurrent Laryngeal Nerve Caused by Syphilis.*—Such a condition causing paresis or paralysis would have responded quickly under specific treatment; there was no improvement in this case.

5. *Final Diagnosis of Hysterical Aphonia.*—This was made because of restoration of voice after the administration of an anesthetic to an individual who probably had latent syphilis.

Cost of Preventable Illness.—The cost of sickness in the state of Illinois for the year ended July 1, 1918, reached the total of $154,881,685, according to a statement issued, January 16, by Dr. C. St. Clair Drake, director of the state department of public health. In the order of their annual cost to the state through sickness and death the several diseases embraced in the study rank as follows: tuberculosis, $114,905,500; pneumonia, $30,909,360; typhoid fever, $3,006,900; malaria, $2,660,860; diphtheria, $1,156,625; whooping cough, $735,220; smallpox, $675,600; infantile paralysis, $461,600; measles, $456,020; epidemic spinal meningitis, $425,700; scarlet fever, $388,300.

TREATMENT OF THE PNEUMONIC DISTURBANCE COMPLICATING INFLUENZA

THE TRANSFUSION OF CITRATED IMMUNE BLOOD

C. W. ROSS, M.D.
Lieutenant Commander, Medical Corps, U. S. N.
AND
ERWIN J. HUND, M.D. (San Francisco)
Lieutenant, Junior Grade, Medical Corps, U. S. N. R. F.
MARE ISLAND, CALIF.

An emergency hospital was established to care for the employees of an industrial plant during the recent influenza epidemic, and in all, 285 cases were cared for in the unit.[1] Unfortunately, the majority of the patients were of the lower type, with environments of poor home and personal hygiene, physically derelict. Many had no care, and suffered even neglect, before admittance. We were thus confronted with a great number of neglected, seriously ill, not a few of whom were moribund. It was a most discouraging circumstance to stand by and observe a death rate of more than 42.9 per cent. in the so-called pneumonias with the various treatments used. We were stimulated to attempt the practical application of theory, and are gratified over a result far beyond our fondest expectations.

While much has been done on the etiology, especially from a bacteriologic standpoint, even to the extent of producing a questionably similar disease in monkeys, by the introduction of a coccobacillus (Plasencia[2] of Havana), we are at present less justified in ascribing influenza to any one particular identified micro-organism than we are in ascribing scarlet fever to a streptococcus infection. However, we must all concede that we are dealing with an extremely virulent intoxicant of uncertain origin.

The clinical course indicates that the intoxicant acts in the main on the central nervous system, as is manifested by: (*a*) prostration with an apathetic state; (*b*) disturbed heat mechanism; (*c*) a central type of gastro-intestinal disturbance; (*d*) peripheral sensory nerve disturbance; (*e*) vasomotor disturbance without evidence of myocardial insufficiency, and (*f*) depression of the respiratory center.

Meyer and Gottlieb[3] thus write concerning the relation of circulatory failure to vasomotor paresis:

> Circulatory failure resulting from vasoparesis occurs in advanced stages in many toxic conditions where altered excitability of the medulla obtains. It was formerly considered due to a cardiac weakness. However, Romberg and his co-workers have correctly insisted that in the course of infectious diseases, disturbances of the circulation develop which closely resemble the picture seen in vasomotor paresis. Using pneumococci and diphtheria as well as pyocyaneus cultures, they were able to show experimentally that at any rate during a long period, during which the blood pressure continued to fall, this was chiefly due to a vasoparesis and not to any direct harmful action on the heart (Romberg, Passler, Bruhns, Müller, Passler and Rolly), and the same holds true in experimentally produced septic peritonitis (Romberg and Heinecke).

That this phenomenon of vasoparesis is early established in this disease is clinically seen by the slow, low tension pulse, early congestive cyanosis, hyperemia of the viscera, especially those rich in vascular supply, epistaxis nasae and gastro-intestinalis, with a concomitant good status of the myocardium.

Associated with this vasoparesis, there undoubtedly coexists a circulating inflammatory intoxicant, as is well shown by a destructive type of leukopenia (a high Arneth's scale). These factors co-working explain the almost universal finding of a hemorrhagic transudate into the richly vascular tissues, and such a status, that is, one in which lowered resistant powers must obtain, predisposes toward secondary infection by well known organisms, such as the streptococcus, pneumococcus and influenza bacillus, especially when the entrance is through simple channels, such as the upper and lower respiratory passages.

In cases progressing to a fatal termination, the clearness and certainty of this interpretation is well shown. The vasoparesis, the blood destruction (leukopenia and lessened coagulability) progress to extreme degree, while the myocardium is disturbed only to a minor degree, and stimulation of the latter may produce in reality an active diffuse pulmonary hemorrhage. The patient expires from a drowning process and respiratory failure, unless there previously existed a severe acute or chronic myocardial condition which might be the cause of death, or a contributory cause.

That all cases of influenza demonstrate the foregoing phenomena to a certain degree is well established. That some cases progress a bit farther to a so-called pneumonia from which the patients recover without treatment is also well established. From this, it is fair to assume that recovery depends on the presence of natural protective elements in the circulation and tissues.

TABLE 1.—ACTIVITIES OF THE BLOOD

Blood	1. Physiologic activity	1. Stimulating normal blood production 2. Control of capillary tree—(*a*) Caliber; (*b*) Rate of flow; (*c*) Integrity of the endothelium 3. Coagulability
	2. Immune activity.	1. Active—Leukocytosis, phagocytosis, chematosis, increased complement, etc. 2. Passive—(1) Normal immune content; (2) convalescent immune content
	3. Mechanical activity	1. Dilution 2. Neutralization 3. Elimination

From the foregoing facts and theory, it is evident that a treatment to be logical must be directed in such a way as to (*a*) neutralize or render the intoxicant inert, (*b*) correct the vasomotor paresis, and (*c*) prevent the blood destruction with its destructive leukopenia and lessened coagulability. It is theoretically established that an immunity either active or passive is corrective to such circumstance.

That clinical application of this phase of theory has produced remarkable results, let alone affirmation, is well shown in the work on immune serum by McGuire and Redden[4] and others. However, the experimental work of Herst, S. Solis-Cohen and M. Solis-Cohen[5] gives evidence of bactericidal properties in the uncoagulated blood of immune species such as pigeons, which property ceases on defibrinization of the blood, and the defibrinated blood often acts as a good culture medium for that particular micro-organism. This explains satisfactorily the failure of immune serum in some cases. The introduction of total immune blood either citrated or by direct transfusion will present all of the advantages of serum and theoretically many added factors as seen in the scheme given in Table 1.

INDICATIONS FOR USE

It has been our experience in the observation of the pneumonic complications in this unit and elsewhere that a process once started becomes of a fulminant and rapidly progressive nature. If this circumstance is permitted and the reserve powers are exhausted, treatment of any type is of no avail. The activity should and must be brought into play before the reserve is depleted to any great degree. It is of no consequence to err on the too early application. Briefly, when cyanosis develops and becomes persistent; when toxemia is well established, as is noted in nervous manifestations, destructive type of leukopenia and diminished urinary chlorids; when the pulse diminishes in tension and the first pulmonary signs (which very often come late) are elicited, then the time for transfusion has arrived. Temperature is a faulty guide, especially a drop, for this does not necessarily mean an improvement, and often means a failure of reaction. A slightly elevated temperature, and as we have seen in some cases, a subnormal temperature with marked nervous manifestations, is an ominous sign.

TABLE 2.—RESULTS

	Transfusion	Symptomatic
Cases treated	28	21
Average days ill before admitted	4	3
Average days of transfusion	8	..
Average temperature before transfusion	101.8	103
Average temperature after transfusion	101.2	..
Average white blood count before transfusion	5,020	4,800
Average white blood count after transfusion	7,450	.....
Average white blood count fourth day after transfusion	11,790	.....
Average days until temperature normal	9.5	15
Average days ill	19	20
Average days in hospital	15	17
Recoveries	22	12
Deaths	6, or 21.4%	9, or 42.8%

One transfusion is often not sufficient. If it is found that the anticipated effect of the transfusion is not obtained, we repeat in from twelve to twenty-four hours and again after that time if necessary. The anticipated effects are a walling off or prevention of further progress of the pulmonary disturbance, the lessening of the toxic state, a better circulatory and respiratory tonus, increased leukocyte count, and a suitable temperature. Careful technic, especially in preliminary tests, makes repetition a safe procedure.

Table 2 includes our experimental cases, that is, patients who were moribund at the time of transfusion, and a better understanding and more fairness to statistics will be obtained by the supplementary information obtained from close clinical and technical observation. The features that stand out prominently are: (*a*) the temperature; (*b*) the blood count, and (*c*) the mortality.

The average temperature before transfusion is low because a few of the early cases were of the nonresistant type, with low and even subnormal temperature and muttering delirium at the time of transfusion. The important feature is that the average time for a normal temperature was 9.5 days of illness or 1.5 days after transfusion, while in the symptomatically treated case the normal line was reached about the fifteenth day. As seen below, several of the cases presented the typical curve of crisis.

The blood count is of interest. The desperate cases presented a uniformly low white blood count of from 1,800 to 3,000 and a tendency to lower as the disease progressed. In a few of the cases transfused in a terminal condition no improvement was obtained, but in the responding cases a characteristic curve was obtained, namely, a persistent rise in white blood count, in some cases up to 24,000, until the process was controlled, and then a drop to normal. The cases treated symptomatically presented a white blood count which remained stationary usually between 3,500 and 6,000, a fact which may explain the long convalescence, frequent complications and sequelae. Further, Arneth's index proved to be very high at first, and returned to an approximate normal shortly after transfusion. The mortality rate of 42.8 per cent. for the symptomatically treated cases and 21.4 per cent. for the transfused cases gives a 21.4 per cent. improvement. This would be even better had we excluded our first experimental cases which were beyond help at time of transfusion.

The clinical observation presents a walling off of the process, a more rapid resolution, an earlier relief of toxic symptoms, and a shorter convalescence. Complications and sequelae were practically nil.

TECHNIC

It is of great import as a matter of safety to match carefully the blood of donor and recipient. It is further of great value to perform not alone a Wassermann reaction but a close clinical observation for syphilis. Poorly matched bloods may not alone prove valueless as far as therapeusis is concerned, but may add a disturbing and even destructive process which may prove fatal. Theoretically, incompatibilities in this disease should be of frequent occurrence, and there was much clinical evidence to substantiate this.

TABLE 3.—TESTS OF BLOOD FOR ISOHEMOLYSINS AND ISOHEMAGGLUTININS

Number of tests made	105
Number of incompatibilities	37
Incompatibility due to presence of isohemolysins:	
Serum of donor	8
Serum of recipient	21
Incompatibility due to presence of isohemagglutinins:	
Serum of donor	0
Serum of recipient	7
Incompatibility due to presence of both isohemolysins and isohemagglutinins:	
Serum of donor	0
Serum of recipient	3
Mutual incompatibility:	
Hemolysis by serum of both donor and recipient	2

The controls remained normal in all of the 105 tests.

In Table 3 is given a complete summary of the results noted in testing the blood for isohemolysins and isohemagglutinins for the purpose of giving blood transfusions to patients suffering from pneumonic complications of influenza. The donors in all cases were chosen from a number of persons who had recovered from the disease and gave negative Wassermann tests.

The technic employed was as set forth by Kolmar,[6] and was briefly as follows:

> Specimens of blood and blood cells are thus obtained from both the prospective donor and the recipient: Four or five c.c. of blood are drawn from a prominent vein with a glass syringe, and of this quantity 0.5 c.c. is diluted with 4 c.c. of 1 per cent.

---

6. Kolmer, J. A.: A Practical Text-Book of Infection, Immunity and Specific Therapy, Ed. 2, Philadelphia, W. B. Saunders Company, 1918.

sodium citrate in 0.98 per cent. sodium chlorid solution; the remainder is allowed to clot. The blood cells are thrown down in the citrate solution with the aid of a centrifuge and washed twice with 0.98 per cent. sodium chlorid solution; they are then suspended in 9 parts of 0.98 per cent. sodium chlorid solution—this is the dilution used in the test. The blood serum is then separated from the blood clot with the aid of a centrifuge and removed to a clean, dry test tube.

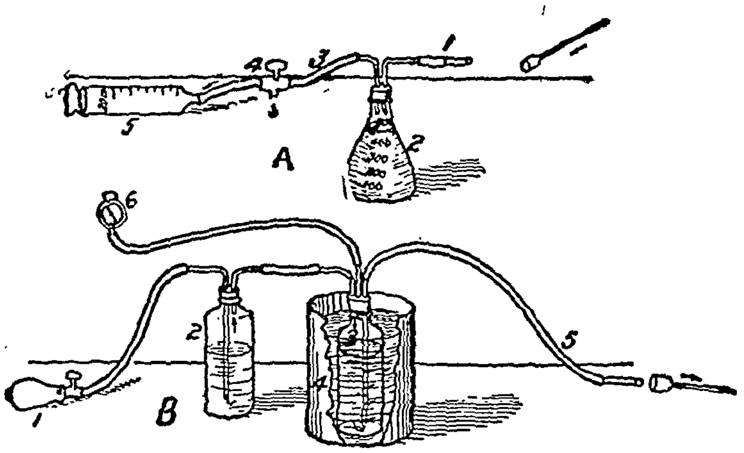

Fig. 1.—Apparatus for transfusion: *A*, receiving apparatus: 1, receiving tube with very short rubber connection (all paraffined); 2, 500 c.c. Ehrlenmeyer flask (paraffined); 3, suction tube for partially exhausting air from flask; 4, two-way stopcock; 5, 20 c.c. syringe; *B*, apparatus for giving blood to recipient: 1, bulb and valve (from sphygmomanometer); 2, wash bottle (containing mercuric chlorid, 1:500); 3, delivery bottle for citrated blood; 4, vessel containing water at temperature of 43 C.; 5, delivery tube; 6, pressure gage (to measure rate of flow and pressure).

The serum and cell suspensions having been prepared as directed with each specimen of blood, the following mixtures are then placed in test tubes (preferably small ones of 15 by 75 mm. size):

Tube 1: Donor cell suspension, 1 drop; recipient serum, 4 drops.
Tube 2: Recipient cell suspension, 1 drop; donor serum, 4 drops.
Tube 3: Donor cell suspension, 1 drop; donor serum, 4 drops.
Tube 4: Recipient cell suspension, 1 drop; recipient serum, 4 drops.
Tube 5: Donor cell suspension, 1 drop; sodium chlorid solution, 0.98 per cent., 4 drops.
Tube 6: Recipient cell suspension, 1 drop; sodium chlorid solution, 0.98 per cent., 4 drops.

Then 1 c.c. of sodium chlorid solution, 0.98 per cent., is added to each tube with a graduated pipet and the tubes are placed in an incubator at 37 C. for two hours or in a water bath at the same temperature for one hour. Hemolysis or agglutination are easily perceived on macroscopic examination. If there is doubt regarding hemolysis, the tubes may be centrifuged. (Tubes 3 and 4 are controls on serum of both donor and recipient, and Tubes 5 and 6 are controls on the erythrocytes and sodium chlorid solution.)

These mixtures should be set up within twenty-four hours after obtaining specimens to obviate danger of deterioration of the native complement. The tubes must be well shaken before being subjected to incubation.

Our work in this unit was done in wards of a supply depot and in tents. In such an emergency, when a surgically clean place is not available, it is essential to avoid air contamination as much as possible. Further, many of our patients were delirious, and therefore direct transfusion was impossible. We chose, by necessity, the citrate method and devised a closed apparatus for giving and receiving blood. Our experience has demonstrated that this procedure is exceeding simple, devoid of danger and readily applicable to bedside conditions.

The receiving apparatus (Fig. 1 *A*) is self explanatory. If a platinum needle of 17 or larger caliber is used, if the flask is well paraffined, if the lead tube and connections are well coated internally with sterile, pure petrolatum, and if the citrate solution in the container is of proper temperature and is shaken gently while receiving the blood, no difficulties should be encountered. The usual surgical technic is employed in controlling the venous supply and the taking of the blood. Care should be used not to cause sufficient vacuum to collapse the vein.

The giving apparatus (Fig. 1 *B*) is also self explanatory. Care should be taken to keep the citrated blood at body temperature, which can be done by keeping the container in a water bath and making the delivery tube as short as possible. The pressure gage is of great value. This will give an index as to rate, volume and pressure of flow, and also any obstruction in the apparatus. It is advisable to work between 40 and 80 mm. of mercury pressure.

The dose of blood varies according to the amount the patient can tolerate. However, owing to the extreme relaxation of the blood vessels and fair state of the myocardium, large amounts may be used in the majority of cases without adding additional stress to the circulatory system. We use from 250 to 500 c.c. of blood at a time, preferably the larger amount. It is advisable to fortify with a hypodermic injection of 1-50 grain of digitalein one-half hour before transfusion. Blood pressure and pulse readings should be performed while the transfusion is in progress; these will give an index as to the amount tolerated by the patient.

The strength of citrate solution used varies with the dose of blood. The larger the dose of blood, the smaller should be the volume and greater the strength of the citrate solution in order not to introduce too large an amount of fluid. A 1 per cent. solution of sodium citrate in physiologic sodium chlorid solution will citrate an equal volume of blood. A 2 per cent. solution in physiologic sodium chlorid solution will citrate two volumes of blood, etc. We use a 1 per cent. solution for a dose up to 150 c.c.; a 2 per cent. for a dose up to 300 c.c.; a 3 per cent. for a dose up to 400 c.c., and a 4 per cent. for a dose of 500 c.c. of blood.

The frequent reaction of a slight chill followed by a profuse perspiration and drop in temperature should be treated symptomatically or merely by support; medication is not as a rule indicated. Should anaphylaxis develop, it is well to use atropin. We always have a hypodermic dose of 1-50 grain of atropin sulphate at hand during transfusion to meet such a development. If the transfusion is given too rapidly, a feeling of constriction in the chest and a slight respiratory distress occur, which cease if the rate of transfusion is decreased. With careful technic, no shock should be encountered.

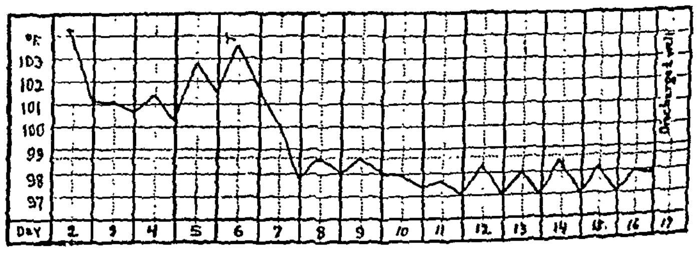

Fig. 2.—Clinical chart, Case 3.

REPORT OF CASES

The accompanying charts and brief histories are of the cases in which transfusion was performed in one of the units. The charts are graphic and note the highest and lowest temperatures, pulse and respirations in twenty-four hours.

Case 1.—C. M. C., a well developed boy of 16, with typical influenza, entered the first day. The white blood count was 2,600. Bronchopneumonia developed the fourth day, and transfusion was performed the fifth day. There was an immediate drop of temperature to an uneventful recovery. The white blood count was from 4,100 to 9,600. The patient was discharged on the twelfth day.

Case 2.—G. I. C., aged 24, with a previous tuberculous history and a typical tuberculous appearance, entered on the sixth day of illness, markedly delirious and cyanotic, with an axillary temperature of 105.4. Physical examination revealed a diffuse bronchopneumonic process. The white blood count was very low, 3,000. The urine contained albumin, and chlorids were in diminished amounts. The blood tension was low and the pulse irregular. A high grade of acidosis was present. Magnesium sulphate was given intravenously, but the clinical picture changed rapidly to the nonresistant form with progressive asthenia, and the patient had a low, muttering delirium. Transfusion was performed on the ninth day. An immediate improvement followed, and the delirium cleared in six hours. The temperature dropped to normal in twenty-four hours and remained so. The patient was discharged on the sixteenth day in a very good state of convalescence.

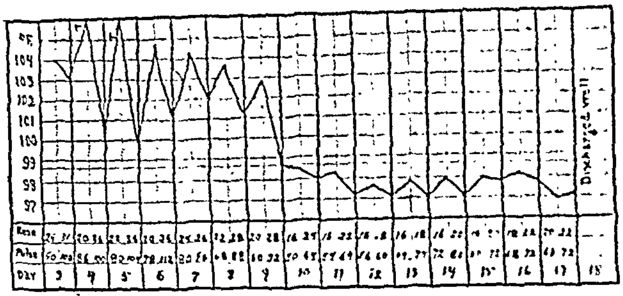

Fig. 3.—Clinical chart, Case 4.

Case 3.—R. J. C., aged 27, in an apparently fair physical condition, entered the hospital, November 7, on the second day of his illness, with typical influenza. The temperature was 104.2. He was given sodium salicylate intravenously with resultant drop in temperature and clearing of the usual influenza symptoms. On the fourth day, cyanosis and pulmonary changes became evident. The temperature rose and clinical bronchopneumonia was well defined. The blood count remained between 2,500 and 3,000. A transfusion was performed on the sixth day, and the temperature dropped to subnormal in twenty-four hours, and remained slightly subnormal until the patient was discharged, in perfect convalescence, on the sixteenth day. The white blood count rose to 5,000.

Case 4.—J. L., a slender boy, aged 17, entered the hospital on the third day of illness with typical influenza symptoms. The white cell count was 9,400. In twelve hours he developed more of a lobar type of pneumonia with faulty consolidation, marked intoxication and delirium. At the time of transfusion the temperature was 106; a twelve-hour drop to 100 and an increase of white cells to 12,750 were noted. A rise in temperature suggested another transfusion, which was followed by a slight reactionary rise to 106. The physical signs here were altered to a fixation of the process; the leukocyte count was 17,051. There was a crisis on the ninth day. An uneventful recovery followed, excepting a slight hematogenous icterus. The blood count returned to approximately normal after the crisis.

Case 5.—W. M. A., a well developed man, aged 39, entered the hospital with typical influenza on the third day. He was given sodium salicylate intravenously without much apparent benefit. Increased cyanosis with acidosis and a progressive bronchopneumonic process indicated a transfusion, which was performed on the eighth day. There was a slight secondary reactionary rise next day, followed by an uneventful recovery. The patient was discharged on the seventeenth day.

Case 6.—H. S., aged 19, anemic, slender and underdeveloped, entered with symptoms of influenza, minus the temperature, on the third day of illness. He was given quinin intravenously on the fourth day with no increase in white blood cells (3,600). Pneumonia developed on the fifth day. Transfusion was performed on the sixth day with a marked reaction. The temperature was 104.4 and rose to 107 in the axilla one hour after transfusion, accompanied by a very violent chill. After reaction, the temperature dropped by lysis. An uneventful convalescence followed. There was a slight secondary rise on the eleventh day when the patient attempted to get out of bed.

Case 7.—R. McC., aged 28, of poor physical status, entered the hospital on the sixth day of illness, actively delirious, dyspneic, cyanotic, and with an axillary temperature of 104.2 Transfusion was performed on the seventh day of illness. The delirium and the general condition cleared somewhat. This patient was tremendously toxic; urinary chlorids were absent, and the blood count was 4,600. On account of the toxicity, an intravenous injection of sodium bicarbonate and sodium chlorid was given. There was some shock with this, as is shown by the rise in temperature, but the toxic state rapidly cleared. Resolution and an uneventful convalescence followed. The white blood count rose from 4,600 to 10,750 after transfusion. The patient was discharged on the twenty-first day.

Case 8.—F. D. U., a boy of slender build and of poor physical condition, aged about 17, entered the hospital on the first day of illness with typical influenza. The white cell count was 5,400. Sodium salicylate was given without effect. On the fourth day he was given magnesium sulphate intravenously. The white cell count was 3,250. The patient got out of bed on the morning of the sixth day. He developed a chill and a rise in temperature with pneumonia of the lobar type. Transfusion was performed on the eighth day with a temperature of 104; the patient was very toxic and cyanotic. There was difficulty in obtaining a donor, and the seriousness of the patient's condition made us use a donor whose red cells were found incompatible. The patient developed marked anaphylaxis, which was controlled by atropin. (The anaphylaxis had been anticipated.) The patient then developed a hematogenous jaundice. There was a clearing up of the physical state and a progressive rise in white blood cells to 22,000. He developed a secondary rash during convalescence. The period of convalescence was prolonged by gastro-enteritis. The patient was discharged well on the thirty-second day.

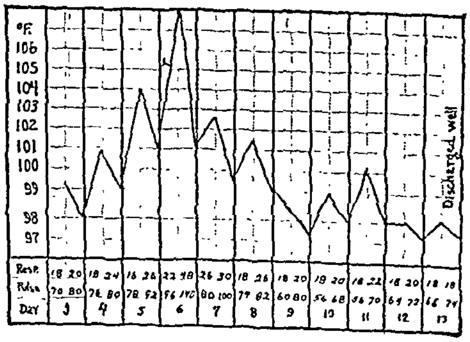

Fig. 4.—Clinical chart, Case 6.

Case 9.—T. W. R., aged 37, a man of the dissipated type, entered the hospital on the third day of illness with typical influenza symptoms. He was markedly toxic, with albuminuria. The temperature was 103.2. The white cell count was 4,100. He developed bronchopneumonia with marked cyanosis and extreme delirium on the fifth day. Transfusion was performed on the sixth day without apparent effect, and again on the seventh day with decline by lysis and a clearing up of physical signs. The patient was discharged on the fourteenth day in perfect convalescence. The white cell count was 7,400. There was a report of pleurisy (?) after discharge from the hospital.

Case 10.—A. A. T., aged 44, of heavy build and good physical condition, entered the hospital on the first day of illness with typical influenza. He was given sodium salicylate intravenously with no apparent improvement. The white blood count was 6,850. Pneumonia developed on the third day, and transfusion was performed on the fourth day. The temperature dropped by lysis, and the symptoms cleared up on the seventh day. The patient was of marked nervous type with delirium. He was discharged convalescent on the twelfth day.

Case 11.—C. T., aged 28, well developed, entered the hospital on the third day of illness with typical influenza symptoms. The white blood count was 2,150. The patient became extremely toxic and cyanotic with definite pneumonia on the sixth day. Transfusion was performed on the seventh day, resulting in a characteristic drop in temperature and a clearing up of the clinical picture. The white blood count was 7,700. The patient was discharged early on account of closure of the hospital. A recent report denotes perfect convalescence.

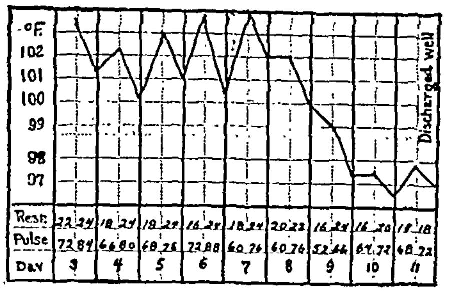

Fig. 5.—Clinical chart, Case 11.

Case 12.—L. F. W., aged 33, obese, entered the hospital with typical pneumonia. He was cyanotic and extremely toxic. The temperature was 104, and respirations were 36, on the third day. The patient showed evidence of marked myocardial and renal insufficiency of long standing, augmented by the present condition. Albumin was ++++. The blood count was 7,950. Transfusion was performed on the fifth day of disease with apparent good result. On the seventh day, however, myocardial insufficiency progressed and the patient died with cardiac rather than the usual respiratory failure.

Case 13.—E. V. R. entered the hospital on the first day of illness with typical influenza. He was in excellent physical condition with the exception of a low blood count, 3,500. Pneumonia developed on the third day. On account of inability to get donors, transfusion was not performed until the sixth day. The patient showed slight improvement but not permanent fixation. He was tremendously toxic, and the transfusion was repeated in twenty-four hours; but the patient became progressively worse and died on the ninth day. The terminal blood count was 2,900. We attribute this death to inability to transfuse in time. Clinically this patient was far better than Patient 14, a parallel case, at the time of entrance.

Case 14.—C. H. entered the hospital with typical influenza on the first day of illness. The temperature was 104.4. Typical bronchopneumonia developed on the fifth day. Transfusion was performed on the seventh day. Uneventful recovery ensued. Temperature was normal on the ninth day. The white blood count increased from 3,150 to 7,740 after transfusion. The patient was discharged early on account of closure of hospital. A recent report states that he is in perfect health.

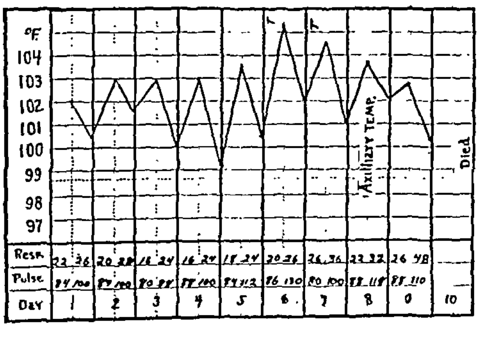

Fig. 6.—Clinical chart, Case 13.

Case 15.—J. A. R., aged 30, of poor physical development, entered the hospital on the second day of illness with typical influenza. He was given sodium salicylate with no results. The white blood count of 5,900 dropped to 2,675. The patient developed a fulminant type of pneumonia, and transfusion was performed while he was moribund on the fifth day. He died on the sixth day.

Case 16.—M. T., aged 41, of the dissipated type, entered the hospital with atypical influenza on the second day of illness. He was given sodium salicylate with no apparent effect. Double lobar pneumonia developed. The patient was extremely toxic and cyanosed, with low muttering delirium. Transfusion was performed while he was moribund. He died on the eighth day.

Case 17.—B. D., aged 39, of poor physical condition and with a history of clinical syphilis, entered the hospital on the third day of illness with typical bronchopneumonia of the nonresistant type. He was actively delirious. Transfusion was performed on the seventh day of illness. The general status, including the delirium, became improved. However, the renal and hepatic insufficiency was of such a degree that elimination was practically nil. Despite the corrective efforts, the patient died on the tenth day. The initial white blood count was 4,150, but rose to 10,900 after transfusion.

Case 18.—H. A. C., aged 43, well developed, entered the hospital with typical influenza symptoms. The white blood count was 2,400. Sodium salicylate was given intravenously on the second and third days with no effect. Pneumonia developed on the fifth day. Magnesium sulphate was given intravenously on the sixth day. The patient was extremely toxic and delirious. Transfusion was performed on the eighth day while the patient was moribund. He died on the tenth day.

Case 19.—G. L. T., aged 42, of dissipated type, entered with typical influenza symptoms, apparently very toxic, on the eighth day of illness. He was given sodium salicylate intravenously with no effect, and this treatment was repeated on the eleventh day with no effect. The white blood count was 5,800. Bronchopneumonia developed on the twelfth day, and transfusion was performed on the fourteenth day. There was a resultant typical temperature curve, and a blood count of 15,000. Resolution developed, but the toxic state remained extreme. The patient was given alkaline transfusion on the nineteenth day, after which the toxemia gradually disappeared. He was discharged to convalescence on the twenty-sixth day.

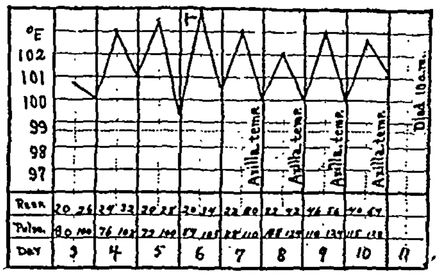

Fig. 7.—Clinical chart, Case 17.

Case 20.—W. L., a well built man, aged 26, entered the hospital on the second day of illness with a temperature of 103, typical influenza, and a white cell count of 6,250. Sodium salicylate was given intravenously without much apparent result. Bronchopneumonia was diagnosed. The left side was chiefly involved on the fourth day of illness. Transfusion was performed on the fifth day. There was a slight secondary rise in temperature. The white cell count was 9,300, with a definite localization of the process. The temperature returned by pseudocrises to normal on the eighth day. Uneventful recovery followed, and the patient was discharged on the sixteenth day.

Case 21.—C., aged 24, and in apparently good previous physical condition, was admitted on the second day of illness with typical influenza. A persistent high temperature, with a low blood count, 3,900, and definite bronchopneumonia indicated transfusion, which was performed on the fifth day. A slight secondary rise followed, succeeded immediately by improvement. The white cell count rose to 7,600. The convalescence was uneventful except for a slight rise due to follicular tonsillitis.

Case 22.—W. R. B., a well developed man, aged 34, was admitted on the third day of illness with typical influenza symptoms. Expectant treatment was used. A rise in temperature on the seventh day with a recurrence of pain suggested the intravenous administration of sodium salicylate. After this, pneumonic signs and a persistent low white count persisted. A transfusion was performed on the ninth day. The temperature dropped to subnormal in thirty-six hours. The physical signs cleared and an uneventful recovery ensued. The patient was discharged on the sixteenth day.

Case 23.—A. H., aged 29, a well developed man who had had apparently no previous physical disturbances of note, entered very ill, November 1, having been ill one day. He appeared slightly cyanotic and dyspneic. Pneumonic complications were anticipated, though the chest signs were negative. The common symptoms, however, were present. Despite a favorable blood count, the pneumonic signs increased, and the clinical course became progressive; also the urinary chlorids were diminished, and general acidosis was marked. A transfusion was performed on the seventh day. The temperature dropped to that of a slightly delayed resolution type. The laboratory and clinical disturbances became restored to normal types on the fifteenth day.

Case 24.—P. McK., aged 35, a well developed man of good physical status, entered on the second day of illness with typical influenza. He was given sodium salicylate with no apparent effect. Pneumonia developed on the fifth day. Transfusion was performed on the sixth day. Uneventful convalescence followed, and the patient was discharged on the thirteenth day.

Case 25.—R. B., aged 20, a man of slender build, entered the hospital on the second day of illness with typical influenza. He was given sodium salicylate. There was a typical influenza curve of temperature. A secondary rise in temperature with diffuse bronchopneumonia was noted on the sixth day. Transfusion was performed on the seventh day with the resultant typical temperature drop and clearing of symptoms. The patient made an uneventful recovery except for slight otitis media. He was discharged on the sixteenth day.

Case 26.—W. H. H., aged 32, well developed physically, presenting a case of toxic type and a white cell count of 5,000, entered the hospital on the second day of illness with typical influenza symptoms. He was given sodium salicylate with apparently good results. On the fourth and fifth days he was given 10 grains of quinin intravenously with no increase in the leukocyte count. Pneumonia developed on the fifth day, and transfusion was performed on the sixth day. The general status and white blood count were much improved, the white cell count reaching 12,900; but the high temperature continued. The temperature became normal on the tenth day, and an uneventful convalescence followed. The patient was discharged on the sixteenth day.

Case 27.—A. J., aged 23, of slender, tuberculous type, entered on the first day of illness with typical influenza. Sodium salicylate was given without effect. The patient developed typical bronchopneumonia of the central type on the fifth day. The white blood count was 2,300. Transfusion was performed on the sixth day. The white blood count was from 4,950 to 9,000. There was a slight secondary rise with decline by lysis. Convalescence was interrupted by pleurisy of the plastic type on the seventeenth day. For four days there was high temperature. The patient was discharged convalescent on the twenty-fifth day.

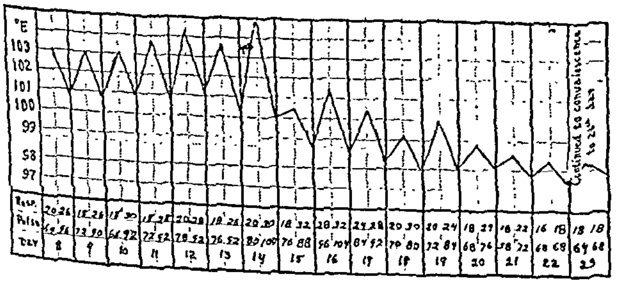

Fig. 8.—Clinical chart, Case 19.

Case 28.—L. D., aged 21, a well built man, entered on the second day of illness with typical influenza symptoms. A typical diffuse bronchopneumonia became evident on the fifth day, and transfusion was performed on the sixth day. An initial drop and secondary rise followed with a resulting clearing up of disturbances. This patient was very toxic prior to transfusion, which condition cleared up early in convalescence. The patient was discharged on the fourteenth day of illness in perfect convalescence.

CONCLUSIONS

1. The cause of influenza is an intoxicant of unknown origin.

2. The clinical course and pathologic physiology indicate that this intoxicant acts primarily on the central nervous system, with especial reference to the medullary centers. Vasomotor paresis is a prominent and constant feature.

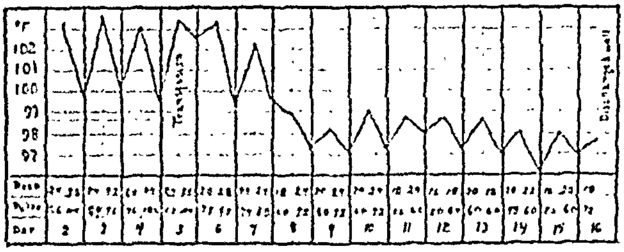

Fig. 9.—Clinical chart, Case 20.

3. Theoretical deductions and practical application affirm that a natural or an acquired immunity is corrective to influenza and its complications. Immune total blood transfusion is theoretically correct, and practical application has affirmed this.

4. The transfusion of total citrated immune blood with proper technic is a very simple and safe procedure.

5. The fulminant nature of the pneumonic complications of influenza demands the very early use of transfusion. Its use is of no avail if the reserve powers of nature have been allowed to progress to an incorrectable degree.

EPIDEMIC MENINGITIS AND DETECTION OF MENINGOCOCCUS CARRIERS *

EDWIN HENRY SCHORER, M.D. (Kansas City, Mo.)
Major, M. C., U. S. Army; Director of the Laboratory Division, Port of Embarkation, Hoboken, N. J., and Officer in Charge, U. S. Army Laboratory, Port of Embarkation, Hoboken, N. J.
NEW YORK

Early after the mobilization of troops, epidemic cerebrospinal meningitis appeared. It was my opportunity to be stationed at one of the cantonments in an endemic area and later to be at the port of embarkation from which most of our troops were sent overseas.

The English had developed means for detecting carriers, but in this country the monograph of Flexner was used largely as the guide. The steps are:

1. Selection of those from whom cultures are to be taken.
2. Taking of cultures with the West tube.
3. Inoculation of veal glucose serum agar.
4. Selection of colonies.
5. Identification of organisms by:
    (a) Morphology in stained specimens.
    (b) Agglutination tests (polyvalent serum and normal horse serum).
    (c) If found to be meningococci, agglutination tests with the various monovalent type serums.

This system we tried to follow, and from it developed our methods. Oct. 16, 1917, we had our first case of meningitis. The laboratory was not equipped, and only Lieut. (now Major) O. F. Broman and I were ready to go to work. We made West tubes, poured plates, and went to the barracks from which the patient

---

* Because of lack of space, this article is abbreviated in The Journal by the omission of certain tables. The complete article appears in the author's reprints.

in the hospital had come. Here we learned that this man had been only one day with his present company, and having no special friends in the company, visited with most of the men. Furthermore, he had been in Company 62-164 D. B. until the day before. When we came to select contacts, we found that we had the company of more than 200 men of Company A, 354th Infantry, and the company of more than 200 men of Company 62-164 D. B., or more than 400 cultures in all to take.

We started at our task and completed it under the greatest of difficulties. The next day cases occurred in other organizations, and cultures of more companies had to be taken. In a very short time we decided that it is hard to determine the contacts in the Army, that friends do not sleep or sit near each other, and that carriers are found to be widely distributed in the company or even in the camp. On these matters we have the concrete data which bear out these assertions, and it is our opinion that to be of most value, companies must be examined for meningococcus carriers when a case occurs. It also developed that taking cultures with the West tube is not feasible or practicable. In place of West tubes we substituted at first only a few nasal swabs, gradually more, and finally we used altogether the nasal swab.

METHOD OF TAKING CULTURES

Thin cotton swabs on small diameter wooden applicators are prepared, and usually ten are sterilized in one test tube. To get the culture the nose is slightly pressed back by the tip, the mouth held open, and then the swab is carried back and downward, usually without touching the sides, clear to the posterior wall of the nasopharynx. Then the swab is rotated and again carefully withdrawn. The plate is inoculated directly with the swab unless there is much mucus, when a spreader is used. Before beginning to take cultures, the men in the company are lined up in two lines, the doors are locked, the windows are closed to get the air as quiet as possible, and a clerk on each side of the table takes the name of the soldier and gives him a number, which number also is used to indicate his culture on the agar plate. Usually the one clerk gives odd numbers and the other gives even numbers. The check list is marked to indicate the organization from which cultures are taken, and it is turned in to the clerk at the laboratory. The medium used at Fort Riley consisted of the regular glucose veal serum agar as advocated by Lieutenant-Colonel Flexner. Later Huntoon's agar to which laked human blood is added to produce a slightly pink color was used and found to produce more and larger meningococcus colonies.

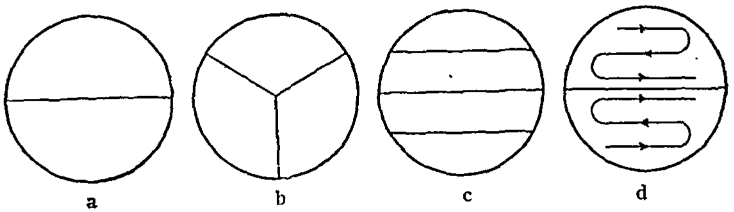

Fig. 1.—Division of plates into sections (*a*, *b* and *c*); method of making inoculation streak (*d*).

When possible, the plates are incubated over night in the inverted position before they are inoculated. As we did not have enough Petri dishes, at first we made cultures from two individuals, later from three, and at times from four on the same plate (of course, we preferred not to use less than one-half the area of a plate for each person from whom a culture was taken). The plate was divided into from two to four sections by marking on the bottom of the Petri dish with a wax pencil as is shown in Figure 1 *a*, *b* and *c*. The segment of the plate is inoculated directly with the swab, unless there is much mucus, when a spreader is used. The inoculation streak is made as is shown in Figure 1 *d* without rotating the swab. The segment is numbered to correspond to the soldier's number on the check list. The plates are kept warm and put in the incubator. The colonies are selected after from eighteen to twenty-four hours' incubation, the small translucent dew drop colonies being ringed with the wax pencil. When several colonies from one segment were selected, the colonies were lettered a, b, and so on. It was soon decided that unless none of the colonies could possibly be meningococci, the most meningococcus-like colonies should be ringed. Slides are then divided into ten spaces and numbered 0, 1, 2, 3 and so on. A drop of distilled water is placed in each segment of the slide, and a key similarly ruled is made on paper; then as a portion of a colony is transferred to the center of a segment on the slide, the soldier's number is put in the corresponding square on the key chart. The plates from which colonies are placed on one slide are put up in one pile. The system may be explained by an illustration (Fig. 2).

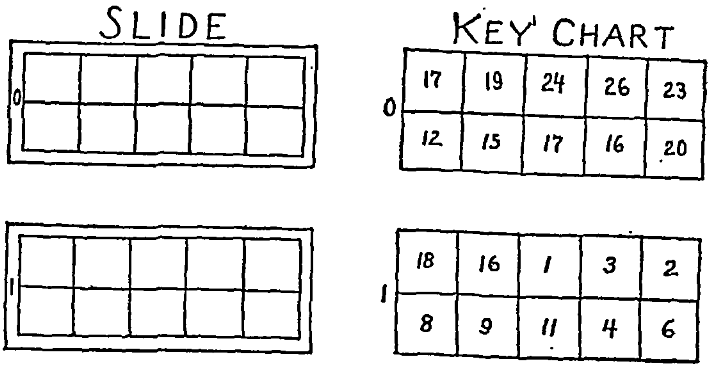

Fig. 2.—System of checking.

After drying, the slides are fixed, and stained by Gram's method, with a counter stain of safranin or Bismarck brown, and the gram-negative diplococci noted.

After going through the plates of a whole organization, the worker has only the numbers of the probable meningococcus colonies to deal with. His list might read like this: 6, 21, 13, 190; and these he may have found on Slides 0, 2 and 18. Then the worker takes from Pile 0 the plate containing Colony 6, from Pile 2 the plate containing Colony 21, and so on. Slants of veal glucose blood agar or veal glucose hormone agar enriched with laked blood are inoculated from what remains of the colonies that are possibly meningococci. The tubes are incubated over night; but if the results must be given at once (that is, within twenty-four hours after taking the cultures), Krumwiede's slide agglutination method is used, that is, finely divided growth is added to polyvalent antimeningococcus serum and to normal horse serum as a control. The growth on the slant medium the next day is washed off in sterile salt solution and added to polyvalent antimeningococcus serum with a final dilution of 1:200, and to normal horse serum with a final dilution of 1:50. We really preferred diluting the serum properly and then mixing in carefully a portion of the agar growth. The tubes are then put in the 55 C. incubator for from four to six hours. If there is agglutination only in the polyvalent antimeningococcus serum, the gram-negative diplococcus is a meningococcus; but if there also is agglutination in the normal horse serum, it is not so regarded.

The technic is satisfactory but tiring. It is possible to train officers readily in the method. At Camp Funston and in the camps of the port of embarkation we had frequently to give results early; but it was regarded better to take out those suspected of harboring true meningococci than to wait until the second day for the absolute, final diagnosis. We may miss a portion of the carriers, but we certainly get those harboring any number of meningococci, and it is essential to remove all the infected men as soon as possible.

As time went on, more cases of meningitis developed at Camp Funston, the disease was occurring in new organizations, and it became evident that we must go still farther to check the disease. As we had been able to accomplish results in the control of meningitis in organizations from which cultures had been taken, it was decided to take cultures of the entire command, about 40,000 troops. This seemed impossible, but it was accomplished.

Six officers from the medical officers' training camp were selected as nasopharyngeal swabbers, nine officers were placed in the laboratory, and the enlisted men worked in day and night shifts. Whether the efforts were worth while and whether it is worth while to get carriers is to be judged from the results obtained and herewith tabulated.

EPIDEMIC MENINGITIS AT CAMP FUNSTON

The first case of meningitis occurred Oct. 16, 1917, in Company A, 354th Infantry. October 17, there were two cases in Company H, 353d Infantry, and one in Company B, 353d Infantry. The cases that occurred and the organizations involved are shown in Tables 1 and 2. In all there occurred, from October 16 to February 3, 148 cases in eighty-three organizations, and two cases in civilians. On the reservation there were at the outbreak of the disease about 50,000 troops in regular organizations of the 89th Division, the 164th Depot Brigade, 13th Cavalry and medical officers' training camp. October 15, there was a considerable interchange of soldiers, men being sent from the 89th Division to the 164th Depot Brigade and from the 164th Depot Brigade to the 89th Division, so that on the day before the first case occurred, men were sent to and from practically every organization in the camp. All of the men except those of the 13th Cavalry were from an area in which meningitis is endemic. In December, the 92d Division (colored) was filled up with men from various parts of the United States, and large numbers of men were sent to the medical officers' training camp. The cases of epidemic meningitis arranged according to months and organizations are shown in Table 1.

TABLE 1.—CLINICAL CASES OF EPIDEMIC MENINGITIS ARRANGED ACCORDING TO MONTHS AND ORGANIZATIONS

Month	89th Division	92d Division	M. O. T. C.	13th Cavalry	Civilians
October, 1917	15	..	..	1	2
November	75	..	..	0	0
December	30	4	1	0	2
January, 1918	12	5	4	..	0
February (3d inc.)	0	0	1	..	0
	132	9	6	1	4

TABLE 2.—CULTURES TAKEN FOR THE DETECTION OF CARRIERS, AND CARRIERS FOUND

Month	Cultures Taken	Carriers Number	Carriers Per Cent.
October (16 to 31 inc.)	4,712	130	2.8
	11,337	532	4.7
	37,435	1,152	3.1
	48,695	1,470	3.0
	102,179	3,290	3.22

In the various organizations, 102,179 cultures were taken. To these must be added the cultures taken for the release of cases and carriers as well as whole wards and nurses and attendants in the hospital.

The cultures for the detection of meningococcus carriers were taken with the results given in Table 2.

Our culture work must be further divided, for we took cultures of organizations: (*a*) when a case occurred; (*b*) in the routine, and (*c*) when a large percentage of carriers was found in an organization. (The carriers were always removed from the organization and taken to a carrier camp. The workings of this will be shown farther on.)

The analysis of results is shown in Tables 3 and 4.

TABLE 3.—NUMBER OF CULTURES AND NUMBER AND PERCENTAGE OF CARRIERS FOUND WHEN MENINGITIS HAD OCCURRED IN AN ORGANIZATION AND ON ROUTINE CULTURE OF THE WHOLE CAMP

Month	After a Case: Cultures Taken	After a Case: Carriers No.	After a Case: Carriers Per Cent.	Routine: Cultures Taken	Routine: Carriers No.	Routine: Carriers Per Cent.
October, 1917	4,712	130	2.8	.....	...	...
November	6,847	258	3.77	2,358	108	4.58
December	2,395	114	4.76	25,711	540	2.10
January, 1918	2,140	91	4.25	38,700	1,298	3.37

TABLE 4.—NUMBER OF CULTURES AND NUMBER AND PERCENTAGE OF CARRIERS FOUND ON ORIGINAL AND RECULTURE IN ORGANIZATIONS IN WHICH A LARGE NUMBER OF CARRIERS WERE FOUND

Month	Cultures Taken: Original	Cultures Taken: Reculture	Carriers Number: Original	Carriers Number: Reculture	Carriers Per Cent: Original	Carriers Per Cent: Reculture
October, 1917	4,712	.....	130	..	2.8	....
November	2,192	2,158	123	52	5.61	2.42
December	1,974	1,908	196	76	9.93	3.99
January, 1918	137	129	10	5	7.29	3.87

These tables, *based on a large number of cultures*, show that generally the percentage of carriers was higher after a case than in the routine cultures. The first complete routine cultures disclosed 3.43 per cent. of carriers, while the second routine cultures on the same troops disclosed 3.02 per cent. A most interesting observation was obtained on reculture when a large percentage of carriers was found in the first culture. While in general less than one-half as many carriers were found, it many times happened that no carriers were found on the second culture. It must, of course, be remembered that the carriers were always removed from the organization. The effects on the epidemic of taking out carriers may be interpreted differently by different observers. For this reason the clinical cases as they occurred are shown according to date of occurrence and according to the organization in which they occurred. Clinical cases arranged according to date of occurrence are shown in Figure 3 and Table 5, and according to organization in Table 6.

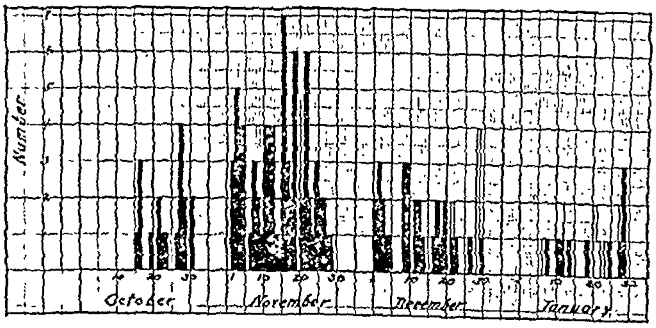

Fig. 3.—Number of cases and dates of occurrence of positive spinal fluid meningitis at Camp Funston, from Oct. 16, 1917, to Feb. 1, 1918: unshaded portion, cases occurring in newly recruited organizations (92d Division); shaded portion, cases occurring in original organizations (89th Division).

Of the 152 cases, four, or 2.6 per cent., occurred in officers, and no cases occurred among medical officers, nurses, or enlisted men in the wards. Four cases occurred in civilians, two being admitted to the hospital in the first day of October, or about two weeks before any soldiers had the disease. There was no traceable connection between these first two civilian cases and the first cases occurring in soldiers.

From October 16 to February 3 is 171 days, and there occurred 150 cases of clinical epidemic meningitis. If this interval is divided into three parts of thirty-seven days each, we find that there occurred seventy-five cases in the first, forty-seven cases in the second, and thirty cases in the third thirty-seven days. But in the third thirty-seven day period only fourteen cases occurred in organizations that had been in camp the first and second thirty-seven day periods. The thirty-seven day periods correspond in the epidemic approximately as follows:

First thirty-seven days, before routine cultures were taken.

Second thirty-seven days, time of first complete routine cultures in the camp.

Third thirty-seven days, time of second complete routine cultures in the camp.

It may be objected that epidemics die out naturally; but in the third period, when new troops came in they came in gradually, so that cultures could be made, and there occurred only fifteen cases in approximately 15,000 troops, as compared to ninety cases in the 89th Division of about 40,000 troops from October 16 to December 1. But even if the spread and severity of the epidemic would usually have decreased, still by taking cultures of whole companies and the routine culture taking of the camp, another very important result was obtained. Sixteen of our carriers developed clinical meningitis, and five more developed sufficient clinical signs and symptoms to have lumbar puncture performed. Nine cases of meningitis with purulent spinal fluid developed in soldiers from whom cultures were taken and who were not detected as carriers; but in at least sixteen cases, by means of our cultures we decreased the probable spread of the disease. According to the thirty-seven day periods this may be presented as in Table 7.

TABLE 7.—PROTECTION AFFORDED BY CULTURES

	Cases of Spinal Fluid Meningitis			
	Total	In Carriers	Organizations Exposed	Per Cent. of Protection
1st 37 days	75	11	64 times	18.7
2d 37 days	47	2	45 times	4.44
3d 37 days	14	3	11 times	27.27

This percentage of protection is a considerable one and indicates that taking cultures after cases and the routine taking of cultures of troops from endemic areas are of value. The development of meningitis in carriers will be discussed later.

Apparent benefits of taking cultures after cases and the routine taking of cultures of troops from endemic areas are demonstrated by these facts: (*a*) Sixteen of the thirty cases occurring from December 24 to February 3 were in newly recruited organizations. (*b*) Repeated cases of meningitis in an organization occurred almost entirely before December 1 (directly after the beginning of routine culture taking).

EPIDEMIC MENINGITIS AT THE PORT OF EMBARKATION, HOBOKEN, N. J.

Most of the troops sent to France, England and Italy were sent through this port. There are two embarkation camps, of which the one at Camp Mills has been under canvas, while at Camp Merritt barracks have been used. In addition to the camps, the Medical Department under Col. James M. Kennedy controls embarkation and debarkation hospitals (nine in number), two post hospitals, General Hospital No. 1 and such part of the Rockefeller Institute Hospital as is used for soldiers. The first case of meningitis occurred in September at Camp Mills. The occurrence in embarkation cases is given in Table 8.

TABLE 8.—CLINICAL CASES OF EPIDEMIC MENINGITIS AT THE PORT OF EMBARKATION, ARRANGED ACCORDING TO MONTHS

	Total	Camp Mills	Camp Merritt	Embarkation Hospitals
October, 1917	1	0	0	1
November	2	0	0	2
December	3	1	1	1
January, 1918	3	0	2	1

August	6	2	3	1
September	3	2	1	0
October	5	1	2	2
November	5	0	4	1
	83	32	26	25

The entire value of taking out the detected carriers cannot be determined, for until about May, 1918, the records of communicable diseases on the voyage overseas were not kept at this office, and the Surgeon-General's Office has no records available on this point. Since June, the ship's surgeon has provided the surgeon at the port of embarkation with a copy of the report delivered to the debarkation officers overseas, and from these reports we learn that two cases of meningitis occurred in organizations from which patients were taken out; but the men were gone from the camps before cultures could be taken. A number of cases occurred on the voyage in organizations from which no patients were taken during the stay in embarkation camps, but none occurred in organizations from which the carriers were removed. Three cases of meningitis occurred in carriers taken out on positive culture.

TABLE 9.—NUMBER OF CULTURES AND NUMBER AND PERCENTAGE OF CARRIERS FOUND WHEN MENINGITIS HAD OCCURRED IN THE PORT OF EMBARKATION

	Cultures Taken	Carriers Found

Total	6,033	158	2.6

CARRIERS

Detection of carriers is of scientific and practical interest only so far as it effects the spread of the disease, as carriers develop the disease, and the manner of clearing up carriers. It is necessary to consider these points, especially as so many officers, without knowing a thing about it, have tried to discredit the value of detecting and removing carriers. That carriers spread the disease can hardly be doubted.

This is true from analogy to other diseases, such as diphtheria, and because taking out carriers certainly seems to have prevented the spread of the disease.

Detectable carriers must be divided into three groups: (*a*) those who are in the incubation period of the disease; (*b*) casual carriers, and (*c*) chronic carriers.

As was stated earlier, by our methods we probably detected the more heavily infected carriers. On those we detected we have considerable epidemiologic data to substantiate the assertion that our carriers were able to spread the disease; and that taking the carriers from the organization stopped the disease in that organization is evidenced by the following concrete cases, of which more could readily be added:

(*a*) In Company C, 356th Infantry, two cases occurred, Nov. 19, 1917, and two, Nov. 22, 1917. Cultures were taken, November 22, 25 and 29. The number of men from whom cultures were taken was 152, 157 and 129, and the number of carriers detected was 7, 9 and none, respectively.

(*b*) In Company A, 340th Field Artillery, 200 routine cultures were taken, November 22, and eleven carriers were detected. November 25, 150 recultures were taken and five carriers detected. November 30, 176 recultures were taken and no carriers detected. November 28 and December 3, two carriers taken out developed spinal fluid meningitis.

(*c*) In Company E, 353d Infantry, November 21 there occurred a case. November 22, 163 cultures were taken and no carriers found, and no further cases occurred in the company.

The development of the disease in carriers has been much discussed. Gates,[1] in his article on antimeningitis vaccinations, says, in his conclusions: "Moreover, agglutinins have been demonstrated in the blood serum of chronic carriers of the meningococcus. Evidence is thus brought forward that the relative immunity of chronic carriers to epidemic meningitis may be due to the presence of specific antibodies in the blood stream." This evidence we do not refute; but some of our detected carriers did have clinical meningitis with purulent spinal fluid. We made many examinations and many kinds of examinations, and from these believe that we have noted different varieties or degrees of epidemic meningitis:

1. Infection in the nasopharynx only or principally. These are our ordinary carriers.

2. Those having the clinical symptoms and signs of meningitis, but clear spinal fluid free from bacteria and polymorphonuclear cells. Five of our detected carriers had sufficient symptoms and signs to have lumbar puncture performed on them, and a very large percentage of our carriers early in the epidemic had severe headache, nausea and fever but cleared up shortly and lumbar puncture was not performed on them.

3. Those having clinical symptoms, clear spinal fluid and no increase in cells, but meningococci in the fluid. Of such cases we observed two: S., Company F, 354th Infantry, and R., Company C, 356th Infantry. That injection of the killed vaccine should, in at least a number of instances, produce severe headache, vomiting (projectile at times) and opisthotonos shows that the endotoxin has a predilection for the meninges, and it is possible that the toxin selects the meninges, injures them, and makes the field fertile for the meningococci already in the blood stream and gives rise to the frank epidemic meningitis with purulent spinal fluid.

4. Those having frank epidemic meningitis. Nineteen of our detected carriers developed the frank type of epidemic meningitis, one developed meningeal symptoms with meningococci in the fluid but no pus cells, and four others developed sufficient symptoms to have lumbar puncture performed. Nine cases of purulent spinal fluid meningitis developed in soldiers missed as carriers on cultures taken less than thirty days and more than seven days before the onset of the disease, and two soldiers missed as carriers in this way developed sufficient symptoms to have lumbar puncture performed. These data when further analyzed may be presented as in Table 10.

TABLE 10.—DEVELOPMENT OF EPIDEMIC MENINGITIS IN SOLDIERS WHOSE CULTURES HAD BEEN TAKEN

	Detected as Carriers		Missed as Carriers	
	Developed Meningitis with Purulent Spinal Fluid	Developed Clinical Meningitis, but No Purulent Spinal Fluid	Developed Meningitis with Purulent Spinal Fluid	Developed Clinical Meningitis, but No Purulent Spinal Fluid
Within 7 days or less after cultures were taken....	19	5	4	2
More than 7 days after cultures were taken..	0	0	5	0
Total...........	19	5	9	2

The incubation period lies between six and twelve days after exposure, so that it is evident that our detected carriers who developed meningitis (purulent spinal fluid and with sufficient clinical symptoms to have lumbar puncture done) were probably not carriers but early cases; and we have no evidence to prove that what are generally known as carriers (especially chronic) develop meningitis. Probably the five carriers who had sufficient clinical symptoms of meningitis had enough toxin to affect the meninges. At Camp Funston about 0.2 per cent. of the troops developed meningitis, while 0.48 per cent. of the detected carriers had the frank form of the disease, or the disease was more than twice as frequent in detected carriers as in all the troops coming from an area in which the disease is endemic. The disposition of carriers is an important factor. At first we sent detected carriers to the hospital; but later they were taken to detention camps where military drill could be continued, that is, the soldiers remained in training. At these detention camps at least once a day silver nitrate solution or argyrol was thoroughly applied to the tonsils and the nasopharynx. However, even without special treatment, about 90 per cent. cleared up very soon after they were taken from the active focus of infection; that is, at least 90 per cent. are only casual carriers. By February 1, out of 3,290 carriers at Camp Funston, only seventy-two, or 2.19 per cent., were found to be chronic carriers. These were all later cleared up by the laryngologists. At the port of embarkation about the same percentage of chronic carriers was hard to clear up as at Camp Funston.

SUMMARY AND CONCLUSIONS

1. Detection of carriers is possible and practical and has marked advantages over quarantining of contacts as has been generally practiced. Cultures of large numbers of troops can be taken with a high percentage of efficiency, and to get the best results it is necessary to take cultures of whole organizations rather than only contacts. The taking of cultures of large numbers of persons at one time has been necessary, and

---

[1] Gates, F. L.: J. Exper. Med. 28: 449 (Oct.) 1918.

at this time we are taking cultures for diphtheria bacilli of all sick and wounded returning from overseas (from 4,000 to 5,000 a week and up to 2,000 at a time) and getting results showing high efficiency of work on a massive basis. There is no evidence that the results on our large numbers of cultures were less accurate than were the results of other workers who took cultures of only a few at a time. In fact, we got better results when we were hard pushed then when we had less work, for when there was much to do the officers were more keen.

2. The taking of cultures of whole organizations or even entire camps need not interfere with military training; taking out the carriers and putting them in a carrier camp interferes less than quarantining even only the contacts.

3. Detecting and taking the carriers out of organizations is of value, and the routine taking of cultures of the whole command seems indicated if the troops come from areas where epidemic meningitis is endemic.

4. Detected carriers have the disease, but our data seem to show that those that developed the disease were already in the incubation period when the cultures were taken. We have no evidence that chronic carriers developed the disease.

5. The cotton swab on a straight wooden applicator, the cultures being taken from the nasopharynx through the nose, gave us good results, and its use is much more feasible than the West tube and bent wire applicators when cultures of large numbers of troops are to be taken.

Sixth Avenue and Eighteenth Street.

THE PATHOLOGIC ANATOMY OF INFLUENZAL BRONCHOPNEUMONIA *

E. R. LeCOUNT, M.D.
Consulting Pathologist, United States Public Health Service
CHICAGO

In this report, based on approximately 200 necropsies, no attempt will be made to distinguish between changes due to the unknown virus and those from mixed or secondary infection; only the most outstanding features are discussed.

Perhaps the most lasting impression from long association with lobar pneumonia in postmortem examination is that when it alone is responsible for death, with very few exceptions,[1] a considerable part of the total pulmonary parenchyma is consolidated, undistensible and heavier than normal; even when limited to one upper lobe, that lobe is as a rule huge, and the lung weight as a consequence frequently doubled.

Therefore, the first feature of the lungs in influenza to attract attention was the relatively small amount of lung tissue solid with grossly demonstrable pneumonia. Even when measured, the total of such regions is so small that it is difficult to ascribe death to the pneumonia with an assurance at all comparable to that with which death is accounted for by lobar pneumonia; in fact, the amount of lung tissue in influenza actually pneumonic seems too little in many cases to explain death by pneumonia. This is best shown by distending the lungs with air, for many of the dark red or purple places, apparently airless and semisolid, balloon out and become quite pink. When surfaces are made by cutting tissues actually pneumonic from influenza, it is not common to find gray or gray-red and finely granular plugs of fibrin and cellular exudate which come away on the knife, as is the case in lobar pneumonia and most bronchopneumonias other than those of the influenzal type. Such surfaces in the nondistensible places in influenzal pneumonia are wet, "velvety" and not granular, but smooth; they resemble raw meat or wet skeletal muscle. The redness of the button-like, firm, superficial regions of pneumonia, likened by some observers[2] to hemorrhagic infarcts, is due perhaps as much to the well-preserved cells of the exudate, many of which are mononuclear, as to the blood content.

However, ranking in importance with the relatively small amount of actually pneumonic lung, or perhaps entitled to first place as a conspicuous feature, is the huge, often thin and watery bloody exudate in the lung tissue and bronchioles. This bloody fluid, on the development of rigor mortis, often pours out of the nostrils so as to stain a large part of the white sheets in which bodies are wrapped. It mainly is responsible for the low level to which the lungs sink when put into water and for the total submersion of some; many are like the lungs of the drowned. The fluid mixed with air and forming a blood-tinged froth is abundant in the trachea, larynx and large air passages after death. Accumulating under the visceral pleura, it makes one of the most interesting and tell-tale signs of influenza; for normally the pleura, fitting the underlying lung tissue snugly as a transparent membrane, allows every detail of the coal-dust mosaic-like markings, as well as the coarser details of the pink, air-containing vesicles, to be clearly seen; but, with the presence of this bloody fluid in the subpleural lymph vessels in abundance so as to distend them, there are produced opaque, reddish brown places, usually a few centimeters in diameter, frequently seen at once when the sternum and costal cartilages are removed. They are so distinctive that influenza is at once suggested as the cause for death; and when no clinical details are known, are highly important clues as to the cause of death. This dissection of the outermost layers of the pleura is very common in the angles formed by fissural surfaces—in the bottom of the cleft. Small hemorrhages in the pleura are also common.

Another feature also due to this bloody exudate is that usually there is some fluid of the kind just described in one or both pleural cavities—more, as a rule, on the side of greater lung involvement. Now, with most pneumonias the pleural exudates are not so blood tinged. With lobar pneumonia they are not only commonly yellowish but also heavy with fibrin; large masses of yellow fibrin wet with plasma often make the lung in lobar pneumonia actually "shaggy"; this I have not seen in influenza. There is commonly some fibrin on the lung, but search is often necessary to find it. It is seldom more than 1 mm. thick, and is often less. The amount of the blood-tinged fluid in the pleural cavities varies widely. When measured, from 25 to 100 c.c. are frequent; larger amounts have been weighed, and the following weights will serve as examples of these exceptional instances: fluid in the right pleural cavity, 840, 345, 860, 600, 320, 930 and 600 gm., each one case; fluid in the left pleural cavity, 900, 1,000 and 320 gm., each one case; 660 gm. in the right with 800 gm. in the left; 1,120 gm. in the right with 1,140 gm. in the left, each one case. These large collections of fluid are in no sense "empyemas." The fluid is only slightly turbid. When time has elapsed for sedimentation after death, the fluid taken for bacteriologic examination, if the pipets are not introduced too deeply, is quite transparent and clear, often with a little of the lilac tint of hemolysis; that collected from deeper layers is turbid.

---

[2] Abstracts of Foreign Literature Compiled by the British Medical Research Committee, J. A. M. A. 71: 1575 (Nov. 9) 1918.

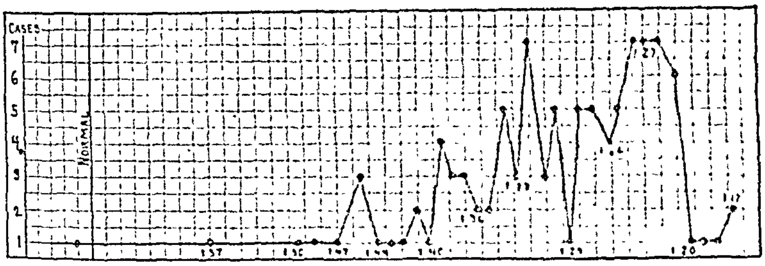

Chart 1.—Ratios of lung weight to body weight in 103 cases of lobar pneumonia from necropsies in 1915 and 1916.

This bloody exudate is not pus in the sense that pus is the product of liquefaction necrosis; there is no suppuration. Postinfluenzal empyema, however, does occur, as well as empyema with repeated thoracentesis. This thin, characteristic, bloody exudate of influenza contains only a little fibrin; or none at all may be visible grossly. It is unlike the pleural exudate of any other form of acute pneumonia with which I am familiar. It reminds one most of the inflammatory exudates in such places as the arm from acute sepsis following wound infection, or the thin, bloody fluid of woody phlegmon of the neck; it is more like exudates due to streptococcus than those we are familiar with in pneumococcus inflammations. The fat of the thymic body and other mediastinal fat, as well as all of the tracheobronchial lymph glands, are also often thoroughly wet with this fluid.

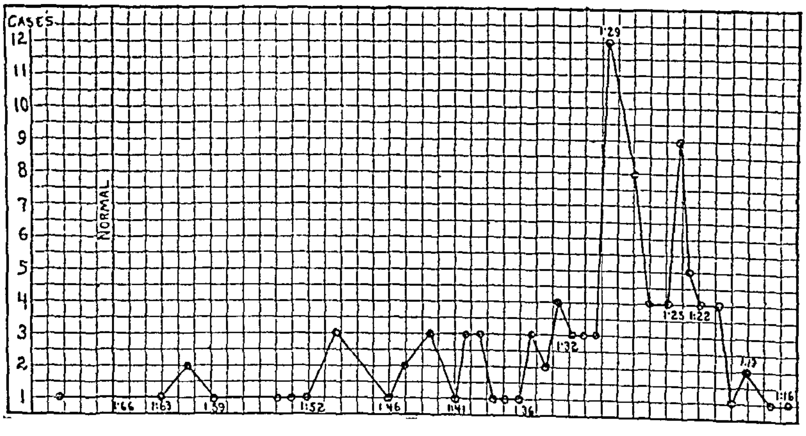

Chart 2.—Ratios of lung weight to body weight in 100 cases of influenzal pneumonia.

Since so much fluid was found in the lungs and as part of an exudate which in many instances escaped into the pleural cavity, less because of pleuritis there than because the lungs, so to speak, "overflowed," the lung weights were compared with the weights of lungs in lobar pneumonia. This comparison is shown by the accompanying charts of the ratio of lung to body weight.[3] From the charts it is apparent that the ratio of lung weight to body weight in lobar pneumonia and influenza are roughly similar; whereas with lobar pneumonia, the precipitate of fibrin is considerable, other parts of the pulmonary parenchyma being compensatorily emphysematous, in influenza, the pneumonia is less and the increased weight due in large part to fluid.

The pneumonia of influenza is commonly referred to as bronchopneumonia. It may be so designated, but it differs from other bronchopneumonias in its predilection for the periphery of the lungs and in the extent to which the inflammation is hemorrhagic.[4] These features, as well as the relatively little consolidation, are well shown by the following account, which may be taken as fairly typical of conditions found with death early in the disease:

> The upper lobe of the right lung is easily ballooned out with air, likewise the middle lobe, so that the black places due to coal dust are very black, the intervening lung tissue pale gray or pink. Except for a place 4 by 2 cm. on the mesial surface of the upper lobe where fibrous adhesions were torn, the pleura is smooth. There are two solid places in the back of the upper lobe, and the pleura covering them is a little swollen. These are 3 by 4 by 5 cm., not at all sharply outlined, with moist gray plugs (hand lens) in the air sacs which cut so as to leave smooth wet surfaces; a thin, watery red fluid comes out of the minute bronchioles in them. The lung tissue around them is very wet but contains air; their bronchi contain a thin fluid with opaque flocculent masses in it. Another similar solid place near the front margin of this upper lobe, 5 to 6 cm. in diameter and 1 cm. from the pleura, has a good deal of blood in it. A solid place is in the back of the lower lobe, like the others but with a layer of fibrin on the pleura over it, as thin as transparent paper. This is also very superficial, and the bronchus to it is full of a frothy, thin, red fluid. A fifth place, from 5 to 6 cm. in diameter, less sharply outlined, with thin fibrin on its pleura and 2 cm. deep (the third dimension), is in the lower lobe near the diaphragmatic surface, which is about one-third covered by fibrin. All the bronchi to this lobe contain these flocculent masses, some adherent to the lining. In the depths of this lobe about the large bronchi there is some consolidation 1 to 2 cm. wide, sharply outlined and deep red. Except in these solid places this lobe distends easily with air, as does the middle lobe, which has no solid places.
>
> The pleura of the left lung is smooth, and both lobes distend completely with air except in two solid places 2 to 4 cm. in diameter, one in the front of the upper lobe and 1 cm. deep, dark red and apparently full of blood, the other in the lower lobe and in all essentials similar. The first of these has sharp margins at lobule septums, and the pleura covering it is raised and translucent. In the smaller bronchioles of the left lung there is a little creamy mucopus.

There was a little slightly turbid bloody fluid in each pleural cavity.

Next in importance as a characteristic of this disseminated pneumonia, hemorrhagic in its early stages and phlegmonous later, is the change in the medium-sized and smaller bronchioles to the involved lung tissue. Early their linings are simply red, their channels filled with a thin, blood-stained froth or fluid; later the linings are necrotic and their content either a thin mucopus resembling that of early gonorrhea or such a mucopus with small flocculent gray or gray-brown masses in it; slight dilatation of the smaller bronchi is common.

---

[3] The normal line is the 1.5 per cent. of the body weight, or 1:66, as given by Vierordt (Anatomische, physiologische und physikalische Daten und Tabellen, Ed. 3, 1906, p. 44).

[4] Symmers, in consequence of the hemorrhages, has compared influenzal pneumonia to that of pneumonic plague (J. A. M. A. **71**: 1482 [No. 2] 1918).

The brain substance is quite regularly swollen, the convolutions of the cerebrum flat; and although this may be evident at once by examining the head first, it is also very well shown by comparing segments made by coronal sections of influenzal brains after hardening in formaldehyd with other brains similarly treated; they are not so swollen as are the brains of septic abortion or other forms of generalized streptococcus infection, nor so pale; but the even external contour and narrowness of the lateral ventricles is a conspicuous feature of influenza; this edema of the brain substance is less than that of uremia or heat stroke.[5]

Still another feature of influenza is that the spleen is not so large as in lobar pneumonia. This statement is a general one and is made without reference to the stage of either disease. The kidneys are regularly the seat of cloudy swelling, and have tense capsules. If any gross alteration of the liver deserves mention as fairly constant, it is the presence of patches of yellow on the front surface due to superficial fatty change.

Less constant are generalized icterus; the early appearance of staining of the lining of large blood vessels by laked blood; patches of necrosis of the larynx or trachea lining; hyperplasia of the lymphoid tissues of the thorax and neck; slight acute serofibrinous pericarditis; acute interstitial emphysema of the lungs and mediastinal tissues, or of these with subcutaneous tissues as well; otitis or accessory (nasal) sinus inflammation, or actual suppuration as small abscesses in the lungs.

It is difficult to believe that a disease with so many distinctive features and affording, as it has, so much of novelty in pathologic anatomy can fail to possess a correspondingly definite etiology.

A more complete report with results of microscopic studies will be made later.

Children in the Connecticut Courts.—Prior to 1917, Connecticut had no special laws governing the trial of children. They were subject to the same legal processes as adults. A law passed in 1917, provides that no child under 14 shall be committed to a jail or common lockup while awaiting trial. In a report on the subject named, prepared by Prof. William B. Bailey of Yale University for the National Children's Bureau, the need for better care of dependent and delinquent children in Connecticut is brought out. Mental examinations to determine the mental condition of delinquent children are rarely had, and repeaters are numerous, until it is determined by a mental examination that such children are feebleminded. In New Haven 692 children were brought before the courts in 1914 and 1915, of whom 672 were boys; most of them for trivial offenses, the most serious being that of a boy of 6 for burglary. The report points out that one fourth of the children brought before the courts in New Haven were from families which had at one time received aid from the associated charities, though the connection between poverty and delinquency is difficult to establish.

THE DIAGNOSIS OF MITRAL STENOSIS

MARCUS A. ROTHSCHILD, M.D. (New York)
Major, M. C., U. S. Army
CAMP DEVENS, AYER, MASS.

Mitral stenosis has not been generally regarded as a common valvular lesion. In the examination of 25,813 soldiers, mitral stenosis was diagnosed in 0.56 per cent., while the diagnosis of mitral regurgitation was made in only 0.43 per cent. In a previous communication, the strict criteria used in diagnosing mitral regurgitation were recorded.[1]

The definite recognition of mitral stenosis is based on the presence of a presystolic or diastolic, apical murmur[2] with or without other classical signs or symptoms. The characteristic type of heart's action is a physical sign of paramount importance. In well-marked cases, when there is hypertrophy, the almost ringing first sound, the accentuated second pulmonic, the small pulse and symptoms, the diagnosis is simple. However, in examining young adults from 21 to 31 sent to the various camps by the local boards, these obvious cases are weeded out. There remains a certain number of cases with no symptoms and no cardiac hypertrophy. The latter group requires very careful study. As a class these men are remarkably free from symptoms, and resent not being allowed the privilege of serving. The pulse rate is slow, the response to exercise usually excellent. The diagnosis rests purely on the presence of a presystolic murmur.

The relationship of a history of acute articular rheumatism in these cases was investigated. In 168 cases we obtained a definite history of rheumatic fever in sixty, or 39.1 per cent. From the remainder, histories of sore throats, scarlet fever, pneumonia, smallpox and other infections were obtained.

In order to obtain some comparative figures, 100 normal recruits were questioned for a history of sore throats. Ninety-five gave a definite history and forty-six of such severity as to confine them to bed. By a comparison of statistics, it was impossible to determine a relationship between previous infection and endocarditis. It is obviously unsound, after determining that a patient has mitral stenosis and has had tonsillitis, to say that the tonsillitis is the cause of the endocarditis.

The recognition of the murmur of mitral stenosis in these early cases requires careful study and examination. It has not been my experience that I have been able to diagnose mitral stenosis after exercise that I have not suspected before exercise. It is true, however, that it has been suspected in far more cases than it has been proved, especially in the recruits with tachycardia. In a recruit with a slow-acting heart, with a snappy or split first sound and a ringing second, unless the soldier is exercised, cases will be overlooked. It is necessary to auscultate in the upright as well as in the reclining posture. It is often of service to have the soldier reclining and well over on his left side in order clearly to bring out the murmur. The variability of the murmur is surprising. It may be heard in any posture,, usually best in the reclining. In one instance, it could not be distinguished with a pulse under 100, but was well audible with a pulse over 100.

---

[1] Rothschild, Marcus A.: The Diagnosis of Mitral Regurgitation (Valvulitis), J. A. M. A. **72**: 327 (Feb. 1) 1919.

[2] The so-called Flint murmur occasionally heard in aortic insufficiency must be differentiated. This differentiation is a matter of extreme difficulty and is based purely on the personal equation. It is my opinion that a presystolic murmur heard in a definite case of aortic insufficiency would better be regarded as evidence of mitral stenosis when there is a definite history of acute articular rheumatism.

There is, however, a group of cases which I have termed, for lack of a better name, "feeling cases of mitral stenosis." In this group, there is no definite mitral stenotic murmur, but a peculiar ringing or split first sound and an accentuated pulmonic second. Two competent examiners will differ as to the exact diagnosis, one saying the soldier has early mitral stenosis, the other "feeling" he will have it. It is in this group that Morrison's amyl nitrite test is of service. The inhalation of amyl nitrite will definitely bring out a presystolic murmur in some of these cases and in others clear up the first sound. In this group, amyl nitrite inhalations are more valuable than the exercise test. The presence or absence of a thrill is of little value because of the danger of confusion of the presystolic thrill of mitral stenosis with the systolic thrill found so frequently in the overacting heart (the neurocirculatory asthenia complex). This condition has been very frequently confused with that of mitral stenosis. The differential diagnosis should not be difficult. In the early case of mitral stenosis there are none of the peripheral manifestations of neurocirculatory asthenia, the cold, cyanotic extremities, the sweating, etc. In the functional cases there are tachycardia, a poor exercise response, marked liability of the heart's action, frequently a change of rate from 120 to 90 from the upright to the reclining posture, and equally labile blood pressure. In the functional case there is a suggestion of a thrill, a snappy first sound with or without a systolic murmur, and an accentuated pulmonic second sound. Exercising these soldiers has given little assistance in differentiating this condition from mitral stenosis, so far as auscultatory phenomena are concerned. In this group, it is important to auscultate during a period of slow heart action. To obtain this we have employed ocular-pupillary pressure with the soldier in the reclining posture. If an assistant exerts sufficient pressure on both eyes, while one is auscultating the apex, the heart will generally gradually decrease in rate from 120 to 60, the first sound will become clear, and the thrill will disappear. When the same reflex is tried in cases of mitral stenosis, the murmur remains unchanged or is accentuated.

It is not possible to demonstrate cardiac hypertrophy in the majority of these early cases, either by location of the apex beat or by percussion. Electrocardiographic studies on ventricular predominance would be of interest.

The lack of subjective complaints in this group is a matter of great interest. Valuable information could be obtained by following a small group of these soldiers through a period of years. Our knowledge of fully developed disease pictures is becoming fairly replete. However, our knowledge of early disease is still scant. More interest should be taken in this wide field of medicine.

CONCLUSIONS

1. Mitral stenosis is not an uncommon valvular disease in men between 21 and 31.
2. Only 40 per cent. of our cases gave a definite history of acute articular rheumatism.
3. The early cases require careful examination, as the murmur is variable.
4. The presence or absence of a thrill is of little value.
5. It must be differentiated from the overacting heart (the neurocirculatory asthenia complex).
6. Ocular-pupillary pressure has proved of great service in differentiating the two conditions.
7. Morrison's amyl nitrite test is of value in proving the diagnosis in cases in which there are slow acting hearts.

New and Nonofficial Remedies

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application. W. A. Puckner, Secretary.

TANNIN ALBUMINATE EXSICCATED-MERCK.—A compound of tannic acid and albumin, thoroughly exsiccated, and containing about 50 per cent. tannic acid in combination. It was first introduced as tannalbin.

Actions and Uses.—Tannin albuminate exsiccated is astringent. Its use is based on the assumption that the tannin would pass the stomach largely unchanged and thus the astringent action be exercised in the intestine where the compound would be decomposed by the intestinal fluid. It is not likely to produce gastric disturbance. It is used in diarrhea, particularly in that of children and in phthisis.

Dosage.—From 1 to 4 Gm. (15 to 60 grains) in powder or tablets followed by water. For infants the dose is from 0.3 to 0.5 Gm. (5 to 8 grains) in gruel or other mucilaginous liquids.

Merck & Co , New York, distributors. No U. S. patent or trademark.

Tannin Albuminate Exsiccated-Merck Tablets, 5 grains.—Each tablet contains tannin albuminate exsiccated-Merck, 5 grains.

Tannin albuminate exsiccated is prepared by precipitating 10 parts of a 10 per cent. solution of egg albumin with 6.5 parts of a 10 per cent. solution of tannic acid, washing the precipitate with water until the washings react only faintly to ferric chloride, drying it on porous tiles, powdering and heating the product to about 125 C. for six hours.

Tannin albuminate exsiccated is a light brown, odorless, tasteless powder, containing about 50 per cent. of tannic acid. It is practically insoluble in water or alcohol, but slowly soluble in alkaline fluids, which decompose it into its constituents.

Shake 0.1 Gm. of tannin albuminate exsiccated for one-half minute with 10 Cc. of water and filter. To the filtrate add one drop of ferric chloride test solution. Only a slight blue coloration is produced (*tannic acid*).

Incinerate 0.5 Gm. tannin albuminate exsiccated. Not more than 0.2 per cent. of ash remains.

Necessity for Attention to Mental Hygiene.—The United States Census Bureau shows that in 1910 there were 187,791 persons in hospitals for the insane and 20,731 persons in institutions for the feebleminded, and that the aggregate cost to the country of the insane alone is more than $160,000,000. On the basis of the lowest estimate there are two insane and four feebleminded persons in every 1,000 of the general population of the United States. Field investigations by officers of the United States Public Health Service indicate that in schoolchildren the ratio of feebleminded will average eight per thousand. Medical examinations of registrants in the first selective draft showed that out of each 1,000 men examined 24 were rejected on account of nervous or mental disorders, and still others developed such disorders under stress of military training and warfare. Many of the dependent and criminal population suffer from some type of mental disorder, either acquired or hereditary. Of 84,198 persons confined in almshouses in 1910, at least 42,000 had some form of mental alienation; of the 136,472 persons in prisons, jails, work houses and institutions for juvenile delinquents, at least 30,000 were mentally diseased. On the foregoing showing it is said in *Public Health Reports*, Jan. 17, 1917, it is high time for physicians and health officers to take an active interest in mental disease as a public health problem.

THE CONTRIBUTION OF HOLIDAYS TO NATIONAL VIGOR

The revolutionary changes that the necessities of the war have injected into our national habits and conventional practices have already become the subject of much speculation with respect to their future states. One often hears the query: "Shall we ever return to our former ways?" Particularly true is this in relation to the educational system, notably among the higher institutions of learning, which have responded in a most extraordinary manner to the nation's call for young men trained intensively in special ways to meet war-time emergencies. There has arisen a concentration of effort and a speeding up of schedules utterly unprecedented in the history of such establishments.

We should not be understood to imply that the outcome of this new way of conducting the business of education necessarily represents a beneficent reform. Undertaken to meet an emergency, it has demonstrated the capacity of our institutions to undergo rapid changes and adjustments of plan and policy. Even before any critical evaluation of the results achieved and the possible advantages gained can be attempted, we hear the prophet declaring that this country shall never again revive the slow and easy methods of the past. The catchword "efficiency" is made to work overtime as the keynote of the expected performances of the future. We are warned that the mistakes of the past must not be repeated; that concentration of attention and conservation of the precious days and years are to become standard aims in the reconstruction period, alike in the world of education and in the domain of commerce.

More than one who have observed the actual working out of the new "militarized" procedures in practice have seriously asked themselves whether in the long run such war-time measures can secure peacetime benefactions. The fact that every hour of the day is utilized does not guarantee that it is most advantageously employed. There is such a thing as intellectual indigestion resulting from inordinate concentration. The efficiency of a mechanical or automatic performance can doubtless be increased in large measure by persistently continued practice; on the other hand, there are more distinctly intellectual processes which become impaired unless a reasonable period for reflection and mental recuperation is allowed.

Let us hesitate, therefore, lest we adopt a machine-like scheme too rashly as the basis for the further development of American higher education. The physician has a special concern in the threatened abolition of the institution of holidays. To him who watches the mode of life of his fellow citizens, the beneficence of an occasional holiday has not escaped notice. It need not be debated whether there has been inordinate waste of time in the past; whether the life of many of our citizens, young and old, has not been extravagant in authorized idleness. The institution of suitable holiday periods is for the most part more than likely to make for good. "The right use of a holiday is one of the sovereign secrets in the practice of the noble art of keeping alive." Let us bear this in mind in the discussion of the projects of reconstruction, frankly admitting that leisure is valuable in the long run only if it improves the quality of work. A change of work may become a holiday in essence. The best holiday is not one spent in languid idleness but one that contains the largest amount of new experience. The physician needs such holidays; and in selecting their routine he will do well to observe such holiday experts as the naturalist, the traveler and the historian, rather than the golfer. A holiday, said a capable observer, is not an end in itself, but a means to a general improvement of the working life. The test of whether a holiday has or has not been well used, he added, is the supplement of zest and vigor that it contributes to our proper labors.

FOOD AND BACTERIA—THE NEW BROMATHERAPY

Alimentary bacteriology is in that interesting evolutionary stage when the light of investigation discloses a new picture of possibilities almost as often as it is turned on the subject. One of the newly discovered situations has been presented in an address to the Philadelphia Pathological Society by Professor Kendall[1] of the Northwestern University Medical School:

> The belief that the intestinal flora is fundamentally a physiologic unit rather than a heterogeneous collection of adventitious microbes has afforded opportunity for a new avenue of approach to this complex subject. Viewed from this angle, the kaleidoscopic aggregation of micro-organisms which comprise the *normal* intestinal flora stands in a rather definite relation to the diet of the host. That is to say, as the diet is changed along definite lines a dual bacterial response may be elicited. The types of bacteria may *and* frequently do shift. Those organisms which cannot accommodate themselves to the new nutritive environment *tend* to diminish in numbers, and other, more adaptable, types take their place. A less spectacular but frequently more signifi-

---

[1] Kendall, A. I.: Recent Developments in Intestinal Bacteriology, Am. J. M. Sc., **156**: 157, 1918.

> cant response is that in which the products of the metabolic activity of the intestinal microbe change parallel with the nutritional stimulus.

There is something decidedly hopeful in the knowledge that of the many varieties of micro-organisms gaining entrance into the alimentary tract few succeed in establishing themselves. The proof that the intestinal tract may become a veritable graveyard for ingested bacteria must spur us on to discover the mechanism whereby the survival is prevented. Foremost doubtless is the fact that most bacterial species have definite rather than promiscuous food requirements or, at least, preferences. Every one knows, broadly speaking, that whereas sugar is readily attacked by yeast it is not so readily decomposed by bacteria. This is a familiar illustration of microbiotic preferences. Contrary to a widespread belief, the bacterial flora of the alimentary tract is by no means a replica of that of the food we eat. The diet of early infancy is rich in carbohydrate in the form of lactose. The *Bacillus bifidus* then establishes itself in the intestine. As the diet changes with age the colon group of bacteria begins to assert itself, not because coliform organisms dominate in the diet but because they, above all others, thrive as well in a medium from which carbohydrates are absent as in one containing them.

The upshot of what has just been intimated is that no implantation of bacteria in the alimentary tract can be expected to prove permanent unless the diet affords a suitable pabulum for the maintenance of the varieties introduced. The remarkable dietary adjustability of the coliform group serves to explain why it is represented to the extent of nearly 60 per cent. of the viable fecal flora. Bromatology and bromatherapy, the science and art of employing food in suitable ways, find a new field in securing intestinal conditions that will lead definite bacterial groups to survive or perish, even in definite regions of the bowel.

Prolonged changes of diet may do more than change the types of surviving intestinal bacteria. Kendall points out that products arising from the utilization of food for energy by intestinal bacteria are of paramount importance in determining the specificity of action of these microbes. To a limited degree a careful modification of the diet may materially alter the character of these metabolic products, with benefit to the host. In the case of the diphtheria bacillus the cultures in suitable carbohydrate contain no toxin, whereas those cultivated under parallel conditions in mediums without carbohydrate are likely to produce considerable amounts of very potent toxin. In the light of such an illustration is it too much to imagine that the flooding of the digestive canal with appropriate foods might be made to reduce radically the alimentary toxicity of adventitiously implanted pathogenic organisms? The carbohydrate-preferring bacteria of the duodenum differ from those of the lower bowel because their favorite food is still available in the upper reaches of the gastro-intestinal tract. To perpetuate the same, perhaps beneficent, types elsewhere calls for insurance of carbohydrate in the lower portions. How this can be accomplished is a problem of the new bromatherapy. As Kendall remarks, intelligent bacterial implantation presupposes an accurate knowledge of the chemistry of the metabolic products of the bacteria under varying dietary conditions. More knowledge is certain to initiate helpful advances in therapy.

A SIDE LIGHT ON THE PROBLEM OF PERNICIOUS ANEMIA

The genesis of pernicious anemia is assuredly still sufficiently obscure to warrant the consideration of it from every promising aspect. The dictum that the hemolysis which is continually taking place in this disease does not differ in kind from that occurring normally or in certain other disorders, but only in degree, gives emphasis to the significant behavior of the blood cells, without affording a new clue to the possible hemolytic agent. Why does hematogenesis become insufficient to replace the lost corpuscles? What is the origin of the poison—the materies morbi which either acts as a hemolytic agent or as a cause of injury to the hematopoietic organs or both?

An interesting suggestion has lately come from the field of comparative pathology. Among horses there occurs a widespread form of anemia which has been associated with the occurrence of larvae of the fly *Oestrus equi* as parasites in the walls of the stomach.[1] The malady is identical with that familiar to French veterinarians as anémie infectieuse. Seyderhelm,[2] working in Strassburg, has demonstrated that injected extracts of the larvae in question can be made to produce a series of symptoms characteristic of the severer types of anemia. The important observation, however, is that although the larvae contain substances that are hemolytic toward red blood corpuscles in vitro, they also yield extracts that can be purified so as to be free from such directly hemolytic agents, yet highly efficacious in producing characteristic symptoms of severe anemia when the product is introduced into the body.

This raises anew the debated question as to whether the actually potent etiologic factor in pernicious anemia is a hemolytic poison or whether the anemia is a consequence of less direct reactions of the causative agent.

Pharmakol. **76:** 149; Wesen, Ursache und Therapie der perniziösen Anämie der Pferde, Arch. f. wissensch. u. prakt. Tierheilkunde **41:** 1914; Experimentelle Untersuchungen über die Ursache der perniziösen Anämie der Pferde, Berl. tierärztl. Wchnschr., 1914, No. 34. Seyderhelm, R.: XVII Tagung der Deutsch. path. Gesellsch., 1914.
2. Seyderhelm, R.: Ueber die Eigenschaften und Wirkung des Oestrius und seine Beziehung zur perniziösen Anämie der Pferde, Arch. f. exper. Path. u. Pharmakol. **82:** 253, 1918.

It has frequently been suggested that the anemia produced by the intestinal parasite *Bothriocephalus* and closely resembling the classic "pernicious" anemia is attributable to a hemolytic lipoid shown to be present in the animal; but objection has been raised to the identification of hemolytic lipoids as the sole cause of blood destruction in the severe anemias, for the organism is well equipped with antagonists to such lipoids. The case of the fly larvae has furnished the highly significant fact that whereas the hemolytic lipoids obtained from them fail to produce any serious illness after introduction into the body, the nonhemolytic fractions of larval substance are exceedingly potent. However promising the lipoid hypothesis has been in the attempt to elucidate the genesis of pernicious anemia, it must no longer be allowed to overshadow consideration of other hypothetic specific poisons, whether they are assumed to be of intestinal, metabolic or entirely extraneous origin.

MALT PREPARATIONS AND CALCIUM METABOLISM IN INFANCY

Malt preparations have enjoyed considerable popularity for some time in the feeding of infants. One of the familiar mixtures is the so-called malt soup, the use of which was modified by Keller of the University Clinic for Children at Breslau to include potassium carbonate. Various claims have been made for seemingly empiric combinations. The assimilability of the malt sugar has been highly lauded, though the evidence for this alleged superiority over other available carbohydrates is by no means overwhelming, however probable it may seem on theoretical grounds. Maltose has been vaguely stated to be indicated in the constipation of infancy. In actual feeding practice, good gains of weight have often been reported as attending the use of Keller's formulas, and the further assertion has been made that the retention of calcium so essential to the growth of the skeleton is thereby facilitated.

How little has been determined definitely regarding the utilization and metabolism of calcium in infancy becomes apparent from the study of the recent controversial literature on the subject.[1] Hence we may be prepared for debated statements with respect to the possible rôle of malt preparations aside from their value as sources of simple carbohydrates. Dubois and Stolte[2] attributed the favorable effect of Keller's malt soup on calcium retention to the alkali that it contains. They argued that the latter contributes to the neutralization of the acids formed in metabolism and thus prevents the loss of calcium for this purpose.

In experiments on animals, Givens and Mendel[3] at Yale University failed to find that administration of a base like sodium carbonate produced any significant effect on the balance of calcium. More recently, Sato[4] has reported from the Department of Pediatrics of Johns Hopkins University that in a normal infant the addition of alkali to milk produces not only no favorable effect on the retention of calcium but a distinctly unfavorable one.

According to Sato, however, malt extract alone without alkali acts beneficially on calcium storage. If malt soup has a favorable effect on calcium metabolism, it is not as a result of the alkali originally contained in it or added to it. Malt extract to which a considerable amount of alkali has been added seems to have a rather unfavorable influence on the calcium balance. There is at present no reason to attritbute the seemingly substantiated benefit of malt preparations on calcium storage to the malt sugar per se. It must be remembered that malt extracts are somewhat heterogeneous in composition. And the statement of Bosworth and Bowditch[5] of Boston that ingestion and absorption of unduly large amounts of calcium salts may under certain conditions of inadvisable feeding promote toxic results in infancy indicates how far we are from final conclusions as to the rationale of the subject.

Current Comment

THE CREATININ CONTENT OF THE BLOOD AS A PROGNOSTIC INDEX IN NEPHRITIS

The improvements introduced in recent years into the methods of analyzing small quantities of blood have made it possible to obtain more exact knowledge regarding many of the chemical changes attending important diseases. Our readers are presumably familiar with the innovations that have contributed to a better understanding in respect to both diagnosis and prognosis in such instances as diabetes, gout, nephritis and uremia. The methods of blood analysis are taking their place side by side with other procedures, such as the phenolsulphonephthalein and related tests, for ascertaining the functional excretory capacity of the kidneys. The damaged eliminating power of these organs seems to be manifested first of all by an increase in the uric acid content of the blood. A greater renal insufficiency is exhibited when there is unmistakable retention of urea. Creatinin is the last of the familiar nonprotein nitrogenous constituents to show accumulation in the blood. In other words, creatinin appears to be the most readily eliminated of the commonly ascertained metabolites. Myers[1] and his co-workers at the New York Post-Graduate Medical School laboratories have argued that, theoretically, the amount of the increase of the creatinin in the blood should be a safer index of the decrease in the permeability of the kidneys than the urea for the reason that creatinin on a meat free diet is entirely endogenous in origin, and its formation (and elimination normally) very constant. Myers and Killian[2] appear to have furnished substantial clinical evidence for the belief that the kidneys are rarely able to overcome "the handicap of a high creatinin accumulation." Out of ninety-four cases of nephritis with blood creatinin values of 5 mg. or more per hundred c.c., improvement almost never followed, and early death was the usual outcome. On the other hand, patients with high figures for urea, but without marked creatinin retention, generally showed improvement. Hence the investigators, who have had exceptional opportunities to study the subject, employing methods that they have long practiced, came to the conclusion that the creatinin data gave them a better prognostic insight into doubtful cases than did either the blood urea figures or the more popular phenolsulphonephthalein tests, which were made simultaneously.

THE APPEARANCE OF LACTIC ACID IN ALKALOSIS

The responses of the organism to a condition of acidosis are becoming quite well known. In order to prevent the hydrogen-ion concentration of the blood from being materially increased, excess of acid radicals in the form of phosphates may be excreted by the kidneys, ammonia may be requisitioned to act as a neutralizing agent, or the alkali reserve of the blood plasma may be called on to combat the tendency to blood changes in the direction of greater acidity. Now that a reverse condition, that of alkalosis, has been described as an actual physiologic and clinical entity, it is natural to inquire as to the possible nature of the acid reserves available when the hydrogen-ion concentration for any reason tends to become less than normal. There is experimental reason for believing that less ammonia appears as an incident to acid neutralization. But according to recent observations by Macleod and Knapp[3] at the Western Reserve University School of Medicine, unoxidized acids, such as lactic acid, also are used for such adjustments in the organism. One might expect that when an excess of alkali is thrown into the blood it would be neutralized by carbon dioxid. The new studies indicate, however, that to prevent an accumulation of carbonates the organic acids may come into play. Thus injection of alkali causes lactic acid to appear in considerable quantity in the urine, and this may occur without any perceptible change in the hydrogen-ion concentration of the blood. The quantity of lactic acid recoverable during the period of alkali injection is insufficient to account for more than 5 or 6 per cent. of the administered alkali. Furthermore, alkali given by stomach in sufficient amounts to cause a disturbance in the acid-base equilibrium of the body, as evidenced by changes in hydrogen-ion concentration, in the ammonia excretion and in the titrable acidity of the urine, causes a slight increase in what is presumably lactic acid in the latter fluid. Evidently the protective devices of the body in such phenomena as the maintenance of the delicate acid-base equilibrium of the body are not yet recognized in their entirety.

MEDICAL COOPERATION IN THE SELECTIVE SERVICE SYSTEM

The second report of the Provost Marshal-General to the Secretary of War covering the operations of the selective service system to Dec. 20, 1918, has just been made available. The interest physicians have taken in the work, and the service they have rendered in the various boards connected with the selective service system, gave assurance that much in this report would concern the medical profession. This prophecy is fulfilled. A few instances: Medicine is credited with supplying 4,246 of the 13,564 members of the local boards (31.3 per cent.); in addition, there were established 155 district boards on each of which there was at least one physician, and 1,319 medical advisory boards with a personnel of 9,577. The organized medical profession will appreciate the following statement:

> At this point a tribute is due to the American Medical Association. From this association came the suggestion for medical advisory boards and cordial assistance in their selection. The Journal of the American Medical Association, with a circulation of 66,000 copies, has been a valuable medium of information between this office and the medical men who discharged the duties of the profession to the government through the draft. The medical profession has responded and served in a devoted manner that has received universally favorable comment. It is gratifying to note the part which the Association has taken in thus assisting to raise our great army, as well as its valuable contribution to the war generally.

THE SUPPLY OF NURSES

In the Correspondence department of this issue are two letters relative to bills recently introduced in the legislature of Illinois to provide for the regulation of nursing. They discuss a question that is of national interest, as is evidenced by letters which have been published from Maine, Rhode Island and New Jersey, and also by radical legislation which has been introduced in Massachusetts. One need at least is clear—a greater supply of well educated nurses must be provided. No doubt a way will be found, without placing too severe a burden on either the nurses, physicians, hospitals or nurse training schools, to provide for the nursing needs of the public, which primarily is interested in the regulations that will be enacted.

Medical Mobilization and the War

Personnel of the Medical Corps

For the week ending February 20, the Medical Corps contained 21,951 officers, a decrease from the previous week of 354. The Medical Reserve Corps contained 763 officers. The total number of medical officers discharged since the beginning of the war is 11,781.

Slightly Wounded

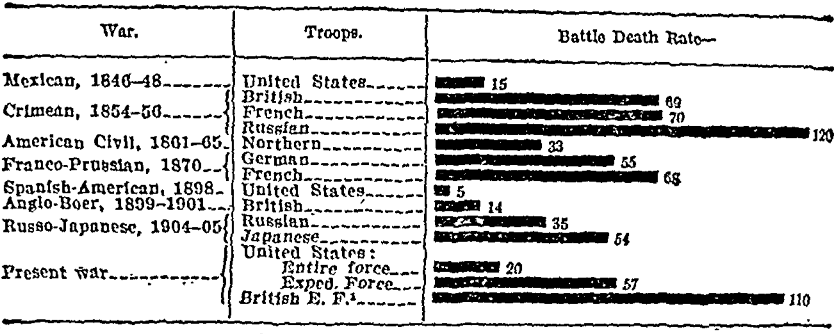
The following medical officers have been reported as having been slightly wounded: Richard S. Magee, Lieut., Altoona, Pa.; James P. H. Ruddy, Lieut., Scranton, Pa.; Fred A. Lieuallen, Capt., Portland, Ore.; Edward J. Meley, Lieut., Ludlow, Pa.; Ray H. Humphrey, Capt., Union, N. Y.; Emanuel Goldstein, Major, Brooklyn; William O. Kleinstuber, Lieut., Wilmington, Del.; Frank T. Duffy, Lieut., Charleston, Ill.; Frank Hurwitt, Capt., St. Louis; Thomas L. Doyle, Lieut., Tremont, Pa.; Alexander W. Seibert, Lieut., Washington, Mo.; William H. Sloan, Lieut., Garland, N. C.; George C. Skinner, Capt., Cedar Rapids, Iowa; William George Byrd, Capt., Belzoni, Miss.; Royal H. McCutcheon, Capt., Franklin, Va.; Raymond Lynde Wadhams, Capt., Wilkes-Barre, Pa.; Jerome Meyer, Lieut., Uniontown, Ala.; George M. Shewalter, Lieut., Indianapolis; Charles James Roach, Lieut., Zanesville, Ohio; Charles Edward McClelland, Major, Columbus, Ohio; John S. Rakin, Capt., Portland, Ore.; Joseph T. Brennan, Lieut., Vichy, Mo.

Wounded, Degree Undetermined

The following medical officers have been wounded (degree undetermined): Edgar W. Roberts, Capt., West New York, N. J.; William Bransford York, Lieut., St. Louis; Richard Sharpless Davis, Major, Germantown, Philadelphia; Renel A. Pierce, Lieut., Mass. N. G., Taunton, Mass.; Eli B. Moss, Capt., Chicago; Theodore L. Pulvermacher, Lieut., Brooklyn; Lawrence L. Keller, Lieut., McMinnville, Tenn.; Lloyd R. Mace, Lieut., Hollywood, Calif.; Arthur Blaine Gjellum, Capt., Brighton, Colo.; Samuel L. Ridge, Capt., Langhorne, Pa.; Albert Herman Hundermark, Lieut., Chicago; Israel Laurier, Lieut., Worcester, Mass.; William C. Stiff, Capt., Plymouth, Pa.; William V. Kane, Lieut., Lynn, Mass.; Henry K. Dillard, Capt., Philadelphia; Claude C. Lyon, Lieut., Logan, Ohio; Edwin Wilson Goodman, Capt., Jersey City, N. J.; Gustave E. Eck, Capt., Lake Mills, Wis.

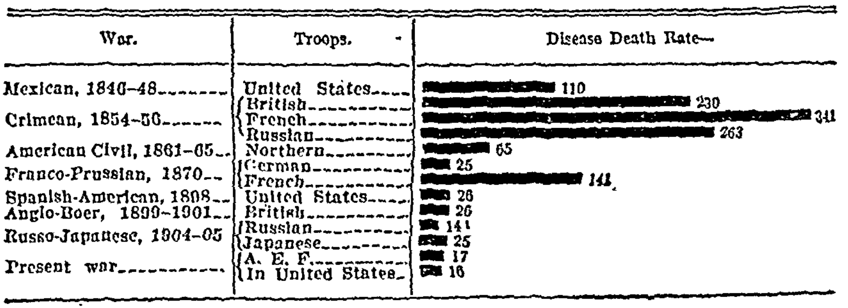
Death Rates in Disease and Battle

In his interview, published Saturday, February 15, in the *Official Bulletin*, General March calls attention to the report of disease and death rates issued by the statistics branch of the General Staff. The death rate from disease among our troops in this war was lower than in any previous war, and this is the first war in which the United States has been engaged in which fewer men were lost from disease than from battle. The low disease rate is attributed in part to the inoculation of troops against certain diseases. Had it not been for the influenza epidemic, the rate would, of course, have been much lower. In the total forces the battle death rate was 20 per thousand per year; the rate of the Expeditionary Forces alone is 57 per thousand per year, which is *one half* of the annual death rate in the British Expeditionary Forces. The accompanying charts, taken from the *Official* Bulletin of February 17, give further figures relative to comparative disease and battle death rates in the present and in previous wars.



¹ Estimate based on incomplete data.

Chart 1.—Battle death rates per thousand per year in recent wars. Accurate strength figures for previous wars are difficult to obtain. In most cases the rates given are probably based on total forces under arms. In this and the accompanying charts, the source of information has been: Comparative mortality of Disease and Battle Casualties (*Seaman Prize Essay*), Capt. L. C. Duncan, M. C., U. S. Army; G-1, G. H. Q., A. E. F.; Statistical Division, A. G. O., and Division of Sanitation, S. G. O.



¹ Based on doubtful data.

Chart 2.—Disease death rates per thousand per year in recent wars.

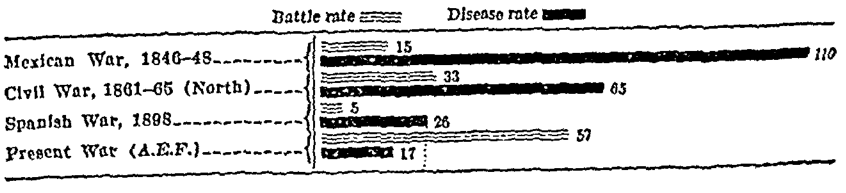


Chart 3.—United States battle and disease death rates per thousand per year.

Prisoners Released

The following officers reported as prisoners have been released from the German prison camp: E. J. Presper, Capt., Philadelphia.

HONORABLE DISCHARGES, MEDICAL CORPS, U. S. ARMY

NOTE.—In the following list, L. signifies lieutenant; C., captain; M., major; L. C., lieutenant-colonel; Col., colonel; and B. G., brigadier-general.

ALABAMA

Albany—Murray, M. W. (M.)

ORDERS TO OFFICERS OF THE MEDICAL CORPS, U. S. ARMY

Alabama

To Camp Sherman, Ohio, base hospital, from Hot Springs, Lieut. C. H. DRAKE, Birmingham.

To Fort Oglethorpe, from Camp Devens, Capt. J. H. EDMONSON, Birmingham.

Arkansas

To Arcadia, Fla., Carlstrom Field, from Lonoke, Lieut. D. R. WILSON, Fayetteville.

To Camp Pike, Ark., base hospital, from Camp Logan, Capt. J. E. CASHIN, Dierks.

California

To Camp Beauregard, La., from Camp Kearney, Major G. D. FRANCE.

To Camp Devens, Mass., base hospital, from Camp Meade, Lieut. D. E. SHEA, Los Angeles.

To Denver, Colo., from Vancouver Barracks, Capt. O. O. YOUNG, Whittier.

To Fort Douglas, Utah, from Camp Lewis, Capt. W. C. MABRY, Tropico.

To Fort McDowell, Calif., from Camp Kearney, Major C. M. HUNTER.

To San Francisco, Calif., from Camp Lee, Major A. J. WILKINSON, San Diego; Capts. M. H. ETCHEVERRY, San Francisco; G. S. HERBERT, Santa Paula. Letterman General Hospital, from Camp Dix, Capts. C. W. MACK, Livermore; S. BUNNELL, *San Francisco; from* the Surgeon-General's Office, Major W. B. BOWMAN, Los Angeles.

To Washington, D. C., and on completion *to San Francisco, Calif.,* Letterman General Hospital, from Camp Dix, Lieut.-Col. H. C. NAFFZIGER, San Francisco.

Canal Zone

To Philippine Department, from Camp Sheridan, Lieut. W. B. FOSTER, Jr., Ancon.

Colorado

To Fort McHenry, Md., from Fort Logan, Lieut. C. W. METZ, Denver.

To Fort McPherson, Ga., from Fort Bliss, Lieut. L. G. BROWN, Colorado Springs.

The following order has been revoked: *To Camp Gordon, Ga.,* base hospital, from Camp Sherman, Lieut. G. L. SHARP, Colorado Springs.

Connecticut

To Cape May, N. J., from Camp Dix, Lieut. H. G. JARVIS, Hartford.

To New Haven, Conn., from McClellan, Lieut. T. P. MURDOCK, Meriden.

District of Columbia

To Camp Upton, N. Y., from Fort Sill, Lieut. A. F. ROCHE, Washington.

To Hoboken, N. J., from Hot Springs, Capt. A. M. MacNAMEE, Washington.

To New Haven, Conn., from Camp Pike, Major A. G. COMPTON, Washington.

To the retired list, from San Francisco, Col. L. M. MAUS, Washington.

To Walter Reed General Hospital, D. C., from Camp Dix, Capt. J. D. THOMAS, Washington; from Hot Springs, Lieut. F. T. CHAMBERLIN, Washington.

Florida

To Camp Dix, N. J., base hospital, from Camp Jackson, Lieut. R. H. KNOWLTON, St. Petersburg.

To Hoboken, N. J., from Camp Dix, Capt. H. C. VON DAHM, Jacksonville.

Georgia

To Fort McHenry, Md., from Hot Springs, Lieut. M. BLANCHARD, Columbus.

The following order has been revoked: *To San Francisco, Calif.,* from Fort Oglethorpe, Capt. B. MASSEY.

Kansas

To Camp Jackson, S. C., base hospital, from Camp Greene, Major S. H. MARTIN, Cambridge.

To Fort Riley, base hospital, from Fort Des Moines, Lieut. A. LEUCYER, Aurora.

To San Francisco, Calif., as department surgeon, from Fort Riley, Col. E. B. FRICK.

Kentucky

To Camp Sherman, Ohio, to examine the command for cardiovascular diseases, from Camp Pike, Capt. C. D. MORRIS, Louisville.

To Fort McHenry, Md., from Hot Springs, Capt. J. H. HOHNSTEDT, Fort Thomas.

To Hoboken, N. J., from Camp Jackson, Lieut. A. D. ECHERT, Newport.

To Washington, D. C., from Fort Oglethorpe, Capt. G. F. DOYLE, Winchester.

Illinois

To Aberdeen, Md., from Camp Cody, Lieut. N. COPELAND, Chicago.

To Camp Abraham Eustis, Va., to examine the command for cardiovascular diseases, from Camp Pike, Capt. W. H. BURMEISTER, Chicago.

To Camp Custer, Mich., base hospital, from Camp Wadsworth, Lieut. M. J. KOSTREWSKI, Chicago.

To Camp Grant, Ill., base hospital, from Camp Dix, Lieut. C. S. BOWMAN, Alsey; from Camp Knox, Lieut. G. D. BRAND, Chicago.

To Camp Lewis, Wash., as tuberculosis examiner, from Vancouver Barracks, Lieut. V. MAURICAU, Rockton.

To Camp Sheridan, Ala., base hospital, from Hot Springs, Lieut. G. C. CONLIN, Springfield.

To Camp Travis, Texas, from Camp Cody, Lieut. P. D. LYONS, Chicago.

To Camp Wadsworth, S. C., base hospital, from Waynesville, Major W. H. WATTERSON, Chicago; Lieuts. W. S. NEEDHAM, Hanna City; J. L. ANDERSON, Winfield.

To Chicago, Ill., from Camp Dix, Major P. OLIVER, Chicago.

To Eastview, N. Y., from Camp Dix, Major R. M. RITCHEY, Elgin.

To Fort McHenry, Md., from Lakewood, Lieut. O. C. HYSLOP, Chicago.

To Fort Sheridan, Ill., from Camp Pike, Lieut. J. P. O'NEIL, Highland Park; from Camp Upton, Lieut. J. J. McCARTY, Jr., Chicago; from Rockefeller Institute, Lieut. R. A. BUCKNER, Gilman.

To Newport News, Va., as orthopedic surgeon, from Camp Sheridan, Lieut. R. E. DAVIES, Chicago.

To Oteen, N. C., from Waynesville, Major D. W. YOUNG, Paris.

To Philippine Department, from Camp Devens, Lieut. H. W. WATEROUS, Galva.

To Riverside, Calif., March Field, from Vancouver Barracks, Capt. C. L. STEALY, Freeport.

To Rockefeller Institute for instruction in the treatment of infected wounds, from Boston, Lieut. J. L. WEBB, Chicago.

To Whipple Barracks, Ariz., from Camp Beauregard, Capt. E. S. GILLESPIE, Wenona.

The following orders have been revoked: *To Fort Benjamin Harrison,* from Camp Custer, Capt. L. H. DAGGETT, Chicago. *To Fort McPherson, Ga.,* from Camp Wheeler, Lieut. J. W. MILLER, Chicago.

Indiana

To Fort Benjamin Harrison, Ind., from Fort Sheridan, Lieut. F. L. HOSMAN, Indianapolis.

To Fort McHenry, Md., from Hot Springs, Lieuts. E. O. DANIELS, Marion; C. G. MACKEY, Whiting.

To Fort Sam Houston, Texas, base hospital, from Camp Zachary Taylor, Lieut. C. E. QUINN, Burlington.

To Lakewood, N. J., from Camp Upton, Lieut. K. C. FITZGERALD, New Harmony.

To Pittsburgh, Pa., from Hot Springs, Lieut. F. KLEINMAN, Hebron.

To West Baden, Ind., from Lakewood, Capt. C. R. STRICKLAND, Indianapolis.

Iowa

To Camp A. A. Humphreys, Va., base hospital, from Hot Springs, Lieut. C. KAIL, Hartford.

To Camp Travis, Texas, base hospital, from Camp Cody, Capt. J. F. STUDEBAKER, Fort Dodge.

To Camp Wadsworth, S. C., base hospital, from Waynesville, Capt. S. C. BUCK, Grinnell.

Louisiana

To Fort McPherson, Ga., from Camp Dix, Capt. P. G. LA CROIX, Lieut. P. J. CARTER, New Orleans.

Maryland

To Camp Lee, Va., base hospital, from Hot Springs, Lieut. S. N. PILCHARD, Salisbury.

To Fort McHenry, Md., from Army Medical School, Major R. T. TAYLOR, Baltimore; from Hot Springs, Capt. T. R. PAYNE, *Corbett.*

Massachusetts

To Army Medical School, from Fort Oglethorpe, Capt. F. E. WHEATLEY, North Abington.

To Boston, Mass., from Camp Dix, Capt. D. MACOMBER, Newton; from Camp Jackson, Lieut. C. H. LAWRENCE, Jr., Boston.

To Camp Devens, Mass., from Camp Dix, Lieut. C. E. RODERICK, Boston. Base hospital, from Camp Dix, Majors P. E. TRUESDALE, Fall River; E. L. DAVIS, Springfield.

To Camp Dix, N. J., base hospital, from Camp Shelby, Lieut. J. H. TAYLOR, *Boston.*

To Camp Upton, N. Y., from Camp Meade, Capt. R. A. GREENE, Palmer.

To Colonia, N. J., from Army Medical School, Lieut. J. M. GILCREST, Springfield.

To Eastview, N. Y., from Camp Dix, Major J. HOMANS, Brookline.

To Walter Reed General Hospital, D. C., from the Surgeon-General's Office, Capt. B. H. HOLMES, Delavan.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest; such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

Personal.—Dr. George B. Worthington has been appointed health officer of San Diego, succeeding Dr. Carl S. Owen, resigned.

ILLINOIS

Personal.—Leo M. Beilin, Captain, M. C., U. S. Army, Springfield, started for Siberia, February 15, and is to be placed in charge of a unit to combat typhus in the United States base in Siberia.——Dr. John A. Wheeler, Springfield, has been endorsed by the Sangamon County Medical Society as a candidate for commissioner of public health and safety.

Nurses' Bill.—A bill has been presented to the legislature for passage by the nurses of this state. After a conference between representatives of the nurses on one side, and the health department, Chicago Medical Society and Illinois Hospital Association on the other, it was not possible to reach an agreement. Another bill has been prepared for introduction by the Illinois Hospital Association.

Hospital Association Organized.—The Illinois Hospital Association has recently been organized, and the following officers have been elected: president, Dr. Malcolm L. Harris; vice president, Dr. William L. Noble; secretary, Dr. Egil T. Olsen, and treasurer, Dr. Carl O. Young, all of Chicago. The purpose of the association is "to promote the welfare of the sick, to make a study of hospital problems and work out solutions to the best interests of the sick and of the hospitals." The fair treatment of all hospitals in the standardization propaganda will also be taken up by the association.

Antituberculosis Work.—At the annual meeting of the Springfield Tuberculosis Association, February 11, Dr. Lewis C. Taylor was elected president, Dr. George Thomas Palmer, director, and Dr. Lewis C. Taylor and C. St. Clair Drake were elected members of the board of directors, and Dr. George F. Stericker, chairman of the executive committee. During the year the organization has not only retained the high standard of efficiency set for it, but has met the extraordinary war time demand and the further call for help during the influenza epidemic and in addition, has maintained competent and effective visiting nurse service.

Chicago

Personal.—Dr. Frederick A. Besley, formerly consulting surgeon, Second Army Corps, American Expeditionary Forces, who is visiting in San Diego, gave a talk on his experiences in France before the San Diego County Medical Society, February 11.

Opium Dens Raided.—In two raids, made February 18, seven Chinese believed to be agents of the opium trust were captured and $26,000 worth of opium and $20,000 in currency were seized. The raids were headed by W. H. Sage, chief of the narcotics department of the internal revenue division.

MARYLAND

Meetings.—At the regular meeting of the Baltimore City Medical Society, held in Osler Hall, February 21, Brig.-Gen. William S. Thayer, Baltimore, chief consultant of the medical division, and Major-Gen. John M. T. Finney, Baltimore, chief consultant of the surgical division, Medical Corps, United States Army, spoke on the work of their respective departments and were followed by Dr. Elizabeth Hurdon, late of the Royal Army Medical Corps.

Anniversary of Johns Hopkins.—Commemorating the forty-third anniversary of the opening of the Johns Hopkins University, exercises were observed publicly at 11 o'clock, February 22, in McCoy Hall. The principal address was delivered by Dr. George E. Vincent, president of the Rockefeller Foundation, who was introduced by Frank J. Goodnow, the president of the university. The trustees of the university, the faculty, the alumni council, the medical, philosophical and undergraduate students formed into a procession and marched to the hall.

MINNESOTA

Hospital Staff for Duluth Hospital.—A meeting was held in Duluth, recently, to further the organization of the medical staff for St. Mary's Hospital, and a committee consisting of Drs. Edward L. Tuohy, Alexander J. Braden, Clarence W. T. Taylor, Theodore L. Chapman, Emanuel Z. Shapiro was appointed to formulate a constitution.

Personal.—Dr. Edward E. Webber, Chisholm, has been appointed chief surgeon of the Duluth, Mesaba and Northern Railroad with headquarters at Proctor, succeeding Dr. William H. Magie, Duluth.——Dr. Blanche W. Horner, of the Rochester State Hospital, has been appointed assistant physician to the Kenilworth Sanatorium, Kenilworth, Ill., succeeding Dr. Ella Blackburn, resigned.——Dr. James H. Beaty has resigned as city physician of St. Cloud.——Dr. George McL. Waldie, New Bedford, has been elected secretary, and Dr. Wilbur N. Morell, Verndale, a director of the Wadena County Public Health Association.

New Officers.—At the annual meeting of the Upper Mississippi Medical Society, held in Brainerd, February 13, the following officers were elected: president, Dr. Arthur W. Ide, Brainerd; vice president, Dr. Audley V. Fankboner, Motley, and secretary-treasurer, Dr. John A. Evert, Brainerd. The next meeting of the association will be held at Pine River, May 20.——At the annual meeting of the Southern Minnesota Medical Association, held in Mankato, January 21, the following officers were elected: Dr. John Williams, Lake Crystal, president; Drs. Walter E. Sistrunk, Rochester, and Walter J. Richardson, Fairmont, vice presidents; Dr. Henry T. McGuigan, Red Wing, secretary (reelected), and Dr. George F. Merritt, St. Peter, treasurer (reelected).

MONTANA

Personal.—Dr. Olive B. Cordua, Helena, has been appointed state chairman of the movement which the American Women's Hospitals have started to raise $250,000 for relief work in Servia, and she has named as district chairmen, Drs. T. A. Bottors, Belt; Agnes J. H. Doty, Billings; Hazel Freed, Grass Range; Olive M. S. Meany, Plains; Lillian G. Miller, Hamilton; Caroline McGill, Butte; Anna A. C. Owens, Hamilton; Helen C. Roberts, Great Falls, and Alma M. B. Ruble, Columbus.——Dr. Patrick H. McCarthy, Butte, has been reappointed secretary of the Silverbow County Board of Health.——Dr. Arter W. Deal, Lewistown, health officer of Fergus County is reported to be seriously ill in St. Joseph's Hospital, Lewistown.——Dr. Harmon T. Rhoads, Choteau, has been appointed county physician of Teton County.——Dr. Benoni A. Place, Great Falls, has been reappointed physician of Cascade County.——Dr. Joseph A. Piedalue has resigned as health officer of Bozeman.

NEBRASKA

Personal.—Dr. Edgar A. Pickens, Benkelman, has been appointed staff physician at the Lincoln State Hospital, succeeding Dr. Richard H. Spradling, Lincoln, who has been made assistant superintendent. Dr. Spradling in his turn succeeds Dr. N. H. Newell, Lincoln, resigned to take up postgraduate medical work in the East.

New Home for Medical Society.—A fourteen or sixteen story building is to be erected at Omaha this year to be occupied exclusively by members of the medical and allied professions. It will be leased and operated by the Douglas County Medical Society, with the exception of the two lower floors which will be retained for general rental purposes.

NEW YORK

Influenza Sweeps Transport.—The transport *Manchuria* which arrived in this port, February 22, carrying over 4,000 returning troops was swept by an epidemic of influenza during the trip. There were 168 men who contracted the disease, twenty-four of whom developed pneumonia. Four of these died.

Tuberculosis Clinic in Canton.—The first of a series of tuberculosis clinics in St. Lawrence County was held in the Town Hall, Canton, February 14, when twenty-three patients presented themselves for examination. The results of the diagnoses made by Dr. Stanley Wang of New York City were: positive tuberculosis cases, 12; suspicious cases to be kept under observation and reexamined, 5, and negative for tuberculosis, 6.

Syracuse Health Officers' Course.—The next residence course for health officers, under the auspices of Syracuse University, will commence, March 28. This course is not limited to health officers but is open to all physicians who wish to acquaint themselves with the latest developments in public health work. Further information regarding this course and registration blanks may be obtained from Dr. Frederick W. Sears, 602 West Onondaga Street, Syracuse.

Water Supply Improvements at Watertown.—A novel improvement has been carried out at Watertown in connection with the gravity mechanical water filter for the city. For the purpose of reducing the high turbidity of the Black River water a large sedimentation or coagulation basin has been formed out of one of the channels in the river lying between an island and the mainland, by placing dams across the channel at the upper and lower ends of the island, thus providing large sedimentation capacity at very low cost. Alum is applied to the water by a whirlpool device at the inlet end.

New York City

Physicians Association Meeting.—At the meeting of the New York Physicians Association, held, February 27, the paper of the evening was read by Dr. Joseph Fraenkel, on "Internal Secretions."

Influenza in Sing Sing Prison.—A new outbreak of influenza is reported from Sing Sing prison. There were twenty-five prisoners ill with the disease, February 15. Dr. Amos O. Squire, Ossining, the prison physician, reports that during the first epidemic there were ninety patients under treatment and that not one succumbed, though a number contracted pneumonia.

Personal.—Capt. Gouverneur M. Phelps, M. C., U. S. Army, who has worked on all the battle fronts except the Italian, recently returned to his home in this city.——Dr. Stephen Smith celebrated his ninety-sixth birthday, February 19. He is still in good health and only resigned from his position on the State Board of Charities in February, 1918, after having served on the board for thirty-four years.

Class in Roentgenography for Women.—Hunter College for Women offers to give a systematic course of training in the technic of roentgenography. The course lasts from two to three months, and consists of dark room technic, regulation of roentgen ray tubes, principles of machinery, placing of the patient for the various roentgenograms, making the exposures, etc. In connection with this training a thorough course in anatomy and physics is given. Hunter College is the first institution of its kind to offer such a course to women.

War Community Service for Physicians.—Members of the medical profession of this city have been advised that a Convalescent Bureau has been established by the Officers Service Department of the War Camp Community Service at Madison Avenue and Forty-Fourth Street. The object is to offer to any officer of the United States Army, Navy, or Marine Corps, on furlough or after discharge from the service, every opportunity for rest and recuperation in the country. Hospitality is offered in private homes at very reasonable rates and special rates have been secured in out-of-town hotels and country clubs.

Child Welfare Conference.—The New York State Association of Child Welfare Boards recently held a three day session in this city. In welcoming the delegates the acting mayor promised consideration by the city officials of any program agreed on and paid a tribute to the work the child welfare boards were doing. Health Commissioner Copeland advocated government control of milk and deplored the fact that such a large proportion of the hospital beds in New York hospitals were in private institutions. One of the aims of the welfare boards is to secure further legislation to provide for the maintenance of widows and their children, so that widowed mothers would be enabled to give their children better protection. Assemblyman Martin McCue stated that he would do everything in his power as a member of the legislature to advance legislation to make the work of the boards more effective.

NORTH DAKOTA

Trachoma Hospital Established.—The seventh trachoma hospital established by the United States government has been opened in La Moure, under the charge of Dr. Clarence E. Downes.

Personal.—Dr. George A. Carpenter, Fargo, has been appointed superintendent of the Cass County Board of Health. ——Drs. H. Haugen, Tindred; William F. Baillie, Hunter; Howard B. Huntley, Leonard; Horace Clark, Wheatland; Sidney B. Clark, Buffalo; Harry J. Gowenlock, Gardner, and John B. James, Page, have been appointed county physicians of Cass County.

New Officers Elected.—At the annual meeting of the Sheyenne Valley District Medical Society held in Valley City, January 29, Dr. Ross D. Benson, Hannaford, was elected president; Dr. Clinton E. Spicer, vice president, and Dr. Samuel A. Zimmermann, secretary-treasurer.——Devils Lake District Medical Society held its annual meeting in Devils Lake, January 21, and elected Dr. John G. Lamont, Dunseith, president; Dr. Arthur T. Horsman, Devils Lake, vice president, and Dr. George F. Drew, Devils Lake, secretary-treasurer.——At the annual meeting of the Grand Forks District Medical Society held in Grand Forks, January 8, Dr. Gudmund J. Gislason was elected president; Dr. H. J. Montat, vice president; Dr. Henry J. Frieskn, secretary, and Dr. Henry W. F. Law, treasurer.

OHIO

Personal.—Dr. Stephen A. Douglass, superintendent of the Mount Vernon State Sanatorium, who has been in Italy with the American Tuberculosis Commission, has returned and resumed his duties.

Health Certificates for Restaurant Employees.—The Lonz bill now pending in the legislature requires persons employed in restaurants or other places where food is prepared for sale to submit to a semiannual medical examination under the direction of local health authorities, and to present certificates of freedom from contagious or infectious diseases.

Coroner's Elect Officers.—At the annual meeting of the State Association of Coroners, Dr. Theodore C. McQuate, Canton, was elected president; Dr. William C. Heintz, Columbus, vice president, and Dr. Arthur C. Bauer, Cincinnati, secretary-treasurer. A special legislative committee was appointed to draft a bill placing coroners on a salary basis instead of on a fee system.

Committee on Mental Hygiene.—A state organization for mental hygiene is to be formed which will cooperate with the national committee. Preliminary steps have been taken by the appointment of Drs. Erl Baber, Dayton; Emerson A. North, Cincinnati, and Ora O. Fordyce, Athens, as a committee to present a plan for the organization of the Ohio branch of the national association.

OKLAHOMA

Personal.—Dr. G. Fowler Border, Mangum, has been elected secretary of the Greer County Medical Society, succeeding Dr. Thomas J. Horsley, deceased.

Society Reorganized.—The physicians of Comanche County met at Lawton, January 15, and reorganized the Comanche

County Medical Society, electing Dr. Alexander H. Stewart, president; Dr. Francis E. Rosenberger, vice president, and Dr. E. Brent Mitchell, secretary-treasurer.

Sanatoriums for Tuberculosis.—A bill has been presented in the legislature for the equipment and maintainance of six sanatoriums in the state. For this purpose an initial appropriation of $600,000 has been asked for building, and also an annual appropriation of $75,000 for maintenance.

OREGON

Influenza.—No deaths were recorded from this disease in Portland, February 12, and but eleven new cases were reported. All bans were lifted, and for the sporadic cases occurring a rigid two weeks' isolation was to be enforced.

PENNSYLVANIA

Personal.—Capt. Edwin B. Marshall, Annville, who spent over a year in France, has returned home.——Dr. Thomas L., Doyle of Tremont has been decorated with the military cross by King George for gallantry. Dr. Doyle was formerly chief resident physician at the Hahnemann Hospital, Philadelphia.

Hospital Items.—General Hospital No. 17 at Markelton, Pa., has been designated by the surgeon-general for soldiers having pulmonary tuberculosis.——The new hospital built by the Emergency Fleet Corporation, will be converted into a general hospital for the people of Bristol and surrounding districts.——The contract for construction work amounting to $343,000 has been awarded for the erection of four one-story buildings and two two-story buildings at Hamburg, Pa. Large additions are also contemplated for the General Hospital and for the St. Joseph Hospital of Lancaster, Pa.

Philadelphia

Army Hospital Opened.—A new U. S. General Hospital was opened, February 17, and occupies part of the Philadelphia General Hospital and has accommodations for 5,000 service men. The hospital force numbers twenty-seven officers, 225 enlisted men and fifty nurses.

Officers Elected.—The annual reunion and business meeting of the Alumni Medical Society of the University of Pennsylvania was held at the Bourse, February 15, and the following officers were elected: president, Dr. B. Franklin Stahl; vice presidents, Drs. Radcliffe Cheston, Henry D. Jump, Lewis H. Taylor, Wilkes-Barre; Park Weed Willis, Seattle; William L. Harris, Providence, R. I.; Alexander R. Craig, Chicago; historian, Dr. William Pepper, and secretary and treasurer, Dr. Floyd E. Keene.——The following officers for the Philadelphia branch of the society were elected: president, Dr. Henry D. Jump; honorary vice president, Dr. E. F. Smith; first vice president, Dr. Clarence P. Franklin; second vice president, Dr. Paul G. Sartain; third vice president, Dr. John J. Robrecht; corresponding secretary, Dr. Stephen E. Tracy; recording secretary, Dr. William O. Hermance, and treasurer, Dr. Herbert B. Carpenter.

Personal.—Dr. Caroline M. Purnell, of the staff of the Women's Hospital of Philadelphia, has returned from France after spending four months as special commissioner for American women's hospitals.——Dr. James A. Babbitt, who has been in France since May, 1917, with the Friends' reconstruction unit, has been chosen a member of the Red Cross commission to go to Germany to help the 1,200,000 Russian prisoners there to get home.——Dr. Ross Hall Skillern, who for the past six months has been commanding officer of Base Hospital No. 89 in the south of France, has returned home. ——De La Ray Signor, Captain M. C., U. S. Army, who was with the 309th field artillery, having been gassed and having contracted influenza, which compelled him to give up his duties at the front, has been placed in charge of Camp Hospital No. 72 at Chateau-du-Soir.——Lieut. David R. Morgan, who received the Croix de Guerre and four citations for his work as a medical officer with a French detachment, has returned home.

VIRGINIA

Personal.—The following members of the faculty of the Medical College of Virginia who have been in the United States service have returned to their former positions: Dr. Blanton L. Hillsman, Richmond, associate in surgery; Aubrey H. Straus, assistant professor of bacteriology, and Phillip F. Fackenthall, professor of pharmacognosy and botany.——Dr. Edward L. Flanagan, Richmond, has been separated from the Army Medical Corps and has been made full-time health officer of Fairfax County.——Dr. J. Fulmer Bright, Richmond, has been commissioned major, M. C., Virginia Militia.——Dr. V. L. Staton has succeeded Dr. John C. Sleet as epidemiologist of Norfolk.

Election.—At the annual meeting of the Warwick County Medical Society held in Newport News, January 22, Dr. William F. Cooper was elected president, Dr. Aaron Jeffery, vice president, and Dr. Dexter W. Draper, secretary-treasurer. At this meeting final arrangements were made for the unveiling of the Walter Reed Memorial Tablet at the Walter Reed High School.

WASHINGTON

Personal.—Dr. Ivan P. Balabanoff, Tacoma, has presented to the health department of the city of Tacoma a completely equipped ambulance to be used in connection with the Contagious Disease Hospital, in memory of his wife, Dr. Margaret L. Carsley Balabanoff.——Dr. Henry H. McCarthy, Spokane, has been elected president of the state board of health.——Dr. John B. Anderson, health officer of Spokane, was elected state health commissioner, Februray 10, to succeed Dr. Thomas D. Tuttle, Seattle, who is reported to have accepted an offer from the United States Public Health Service.

WISCONSIN

Decision Against "Plaster" Doctor Affirmed.—The Supreme Court, February 5, affirmed the decision of the circuit court, declaring that John Till, the notorious "plaster" doctor of Turtle Lake, was practicing medicine without a license and sustained the sentence of a fine of $250. This man conducted a place near Turtle Lake at which treatments were given for all sorts of ailments, and was accustomed to request each person who came to see him, to sign a card and to pay 25 cents before seeing him. The card was a waiver of all claims for damages arising out of any treatment that he mi[illegible] might omit to give. The district attorney of [illegible] prosecuted Till, charging that he practiced [illegible] a license, and he was found guilty a[illegible] promptly appealed his case.

GENERAL

Roaldes Prize.—The Roaldes prize of the [illegible] gological Association, amounting to $200, is [illegible] in general competition for the best thesis on so[illegible] directly connected with laryngology or rhinology. Papers must be in the hands of the secretary, Dr. D. Bryson Delavan, 40 E. Forty-First Street, New York City, prior to June 1.

New Red Cross Head.—Dr. Livingston Farrand, Boulder, president of the University of Colorado, has been appointed by President Wilson to be chairman of the central committee of the American Red Cross, to succeed ex-President William H. Taft. Dr. Farrand will become executive head of the national Red Cross organization on the retirement of the war council, March 1. On this date the Red Cross will be changed from a war to a peace basis.

Fraternity Dinner.—The Alpha Omega Alpha Honorary Medical Fraternity announces that the three Chicago chapters of the society located, respectively, at the University of Illinois, University of Chicago and Northwestern University, will give a dinner on the first day of the annual Congress on Medical Education and Licensure, March 3, at the Hotel LaSalle, at 6:30 o'clock. Dr. William A. Evans, Chicago, will officiate as toastmaster, and among the speakers will be Dean John L. Heffron of Syracuse University, president of the organization, and Dr. William W. Root, Slaterville Springs, N. Y., secretary-treasurer.

Missionary Health Board.—The joint centenary of the Methodist Episcopal Church announces the establishment of a medical department under the direction of the board of foreign missions to guard health efficiency of its missionary workers. Dr. John G. Vaughan, formerly of Nanchang, China, is executive secretary of the new department with temporary offices at the headquarters of the Missionary Centenary, 111 Fifth Avenue, New York City. Dr. Vaughan has been until recently, a member of the surgical staff of the Rock Island System in Chicago, leaving that position to organize the new medical department of the Methodist Foreign Missionary Board.

Bequests and Donations.—The following bequests and donations have recently been announced:

Philadelphia Home for Incurables, Children's Hospital, Philadelphia Training School for Feeble-Minded Children, and two other charitable institutes, the entire estate valued at $24,000 by the late Justus Branner, after the death of the beneficiary.

Hahnemann Medical College, Philadelphia, a fund of $200,000 for research work in connection with the fight against influenza, by Walter E. Hering, Philadelphia.

Hatfield Memorial Park and Convalescent Hospital, Wagontown, Chester County, with maintenance by an annual trust fund of $10,000, is provided in the will of Mrs. M. F. Hatfield.

Howard Hospital, Philadelphia, $2,000, by the will of Gustavus B. Benson, Jr.

Missionary Hospitals in South America.—Miss Charlotte A. Aikens of New York, editor of the *Trained Nurse and Hospital Review*, has been engaged to make a tour of the Argentine Republic, Uruguay, Chile, Bolivia and Peru, to study the conditions which prevail there and the needs of the field for hospitals. After her report has been received, the number and location of the hospitals and health stations to be established in the five republics as part of the centenary program of the Methodist Episcopal Church will be announced. By interdenominational agreement, these hospitals are placed under the supervision of the Methodist Episcopal Church, which is raising $120,000,000 for world upbuilding and the extension of missionary work.

FOREIGN

Scandinavian Congress for Internal Medicine.—The internists of the Northland, organized in the Nordisk Forening for indv. Medicin, announce that a congress will be held at Copenhagen late in August, 1919. The last meeting of the kind was at Lund in 1913.

Tribute to the Medical Officers of the Italian Army and Navy.—In tribute to the medical officers of the Italian army and navy an imposing ceremony was recently organized at Naples by the *Riforma Medica* to do honor to the medical officer who had been awarded the largest number of decorations for exceptional gallantry and devotion. This was Capt. Raffaele Paolucci, the "hero of Pola." The *Riforma Medica* [illegible]ary 4, reproduces the addresses and the portrait of [illegible] naval medical officer and the trophy presented him [illegible]ng. It represents a silver winged victory, alight[illegible]arble pedestal, with bas reliefs and inscriptions. [illegible]ony was a tribute to the gallantry and devotion [illegible] by the whole of the medical profession on land [illegible]uring the war. It was especially appropriate to have [illegible]ples as Dr. Paolucci is a graduate of the medical [illegible] there. He has a record of good work also in the African campaigns before the great war began.

A Fellowship in Medicine.—At a meeting early in the year at the house of the Royal Society of Medicine in London, presided over by Sir Arbuthnot Lane, a movement was started for the formation of an association for cooperation in medicine among the English speaking physicians of the world. The promotion of a mutual understanding between the medical profession of the United States and the British Empire was the main objective of the movement, which has progressed so far that the Royal Society of Medicine has now issued a cordial invitation to the medical men of the dominions and of America, as well as to the medical men of the allies, to use the buildings of the society in London as the home of a fellowship of medicine with the tentative name, "The Interallied Fellowship of Medicine." The movement has the support of the Director General of the Army Medical Service, the Surgeon-General and others. An account of the meeting at which the organization was launched is contained in *The Lancet*, Jan. 4, 1919.

SOUTH AND CENTRAL AMERICA, MEXICO AND WEST INDIES

Silver Jubilee of the "Semana Medica."—We have been listing the contents and reviewing our Buenos Aires exchange for almost a generation, and the 800 pages of the volume just closed with 1918 finishes its twenty-fifth year of existence.

On the occasion of this silver jubilee a festival gathering was held at the headquarters of the journal with much ceremony and congratulations. The *Semana Medica* was founded by Dr. T. Padilla hijo. The present director is Dr. D. Decoud, professor of surgery at the University of Buenos Aires, and the editorial staff consists of twenty-six professors in the university besides Dr. E. R. Coni, the leading hygienist of Argentina, and Drs. V. Delfino and A. Chueco, the latter chief of the surgical service in the Fernández Hospital. The list of professors includes many names of international reputation, from Penna, Agote and Ingenieros to Boero.

MADRID LETTER

Madrid, Jan. 15, 1919.

Influenza in Spain

Since my last letter, influenza has been ravaging the land, leaving a trail of sorrow and tears. It was at the close of the summer that the country, disturbed and suffering from food privations, agitated by political campaigns and sectarian maneuvers, awoke one morning to the realization that a disease was rapidly sweeping away its people by hundreds. The civilian authorities in certain places were apparently responsible for the blunder of concealing the evil at its beginnings, at a time when it might have been possible to apply the remedy of isolation. San Sebastian, for instance, is a delightful city on the northern coast, close to France, with a populace trained in hygiene, and a model municipal administration. It is the residence of the court during August, September and October, and was full of "resorters" from all over Spain. This city became one of the chief foci of the epidemic, and from there, by the dispersion of its alarmed visitors, the disease spread to other provinces.

CRITICISM OF OFFICIAL MEASURES

The daily papers took advantage of the occasion to play politics, censuring what the government was doing and contributing to the general alarm and worry. All classes of society were victims of influenza, even the king, who had the disease in quite a serious form for a time.

CRITICISM OF CHIEF OF PUBLIC HEALTH SERVICE

The chief of the Public Health Service of Spain, which is subordinate to the ministro de la gobernacion (interior), is the director general or inspector general de sanidad. This position is now held by Dr. Don Manuel Martin Salazar, trained in hygiene in other countries, author of a fine treatise on immunity. He reached his position by the reputation gained from his works and the fact that he had become an authority on epidemics by his successful campaign against several, among others the epidemic of plague on the Canary Islands, at the time when Dr. Pulido was director general de sanidad. Articles were published aiming to create dissatisfaction and distrust. Politics intervened, and charges were preferred, but the government came out victorious as the proceedings brought out in a good light the work done by Dr. Salazar. He has remained in his position. As the tide of politics has swept away for the present the possibility of the appointment of a minister of health as a member of the cabinet, the campaign against Dr. Salazar has been dropped. However, all activity has some use, and the activity displayed by those who have been stirring up public opinion to such an extent has emphasized the necessity for more ample appropriations for the Public Health Service, and has contributed to facilitate the approval by parliament of the expenses incurred in combating the epidemic of influenza.

Interview with Chief of Public Health Service in Spain

In the present circumstances, the most interesting person from a medical point of view is the above mentioned Dr. Martin Salazar. In order to inform the readers of The Journal in regard to his impressions of the epidemic of influenza here, I asked for an interview with him. Dr. Salazar hastened to grant my request for an interview, expressing at the same time his high appreciation for The Journal, of which he is an assiduous reader.

THE TWO PHASES OF THE EPIDEMIC

He emphasized the two epochs of this epidemic, each with its different characteristics. The first phase, that of last spring, was an epidemic of the cities, spreading rapidly and widely but without a high death rate. It conferred positively an immunity. This immunization has benefited the populace of the cities where the disease at first spread so rapidly and widely, as at Madrid, Badajoz and Sevilla. On the other hand, the towns which were spared at the first invasion, such as Barcelona, have suffered most at the second invasion.

THE SECOND INVASION

This second invasion, according to Dr. Salazar, had two beginnings. It commenced, on one hand, in those provinces which have the closest relations with foreign countries and, on the other hand, it broke out in autogenous foci at different points, such as those among the troops. The new recruits in the barracks scattered over the country, formed the main contingents in the first appearance of the epidemic at the close of the summer. This is a phenomenon difficult to be explained unless by the immunity of the older soldiers who had had the influenza in a milder form in the spring, while the new recruits were attacked with the gravest forms of the disease. The barracks at Carabanchel near Madrid, and at La Granja in Segovia had at certain times as many as 3,000 and 4,000 down with the epidemic, and the death rate was high, although it varied widely in different regions. The pulmonary forms were common as also the hemorrhagic forms, and the deaths were sudden.

In the general population, Castellon on the Mediterranean coast was one of the worst foci of the epidemic, while the provinces bordering on France were becoming invaded. The extremely rapid and extensive spread of the epidemic coincided with the return to Spain of the thousands of laborers who had been engaged in the vintage in southern France. The disease spread like dust before the wind, and all parts of Spain, except the south, were affected. The southern provinces are now in the throes of the epidemic. At the same time Portugal was invaded by the influenza, probably brought by soldiers returning from the front in France.

In this way, as in all great pandemics, there were autogenous foci and exotic foci, and there was communication between them in spite of all the strict supervision of the frontiers which was excessive. The inspector general remarked that if he had anything to regret, it was that he had done too much; that, impelled by public opinion, he had gone beyond the limits of the scientific.

CONTAGIOUSNESS OF INFLUENZA

The inspector general de sanidad declared that the disease is so contagious that there is no means of avoiding it. The only differences in the behavior of the disease in different countries are those resulting from poverty and home conditions. Gathering in the harvest was the principal cause of the diffusion of the disease.

PROPHYLAXIS

In these infections, he added, public prophylaxis places all its hope in preventive vaccines. The British vaccine prepared for the army and navy is made with Pfeiffer's bacillus, the pneumococcus and hemolytic streptococci. From the beginning of the epidemic Dr. Salazar planned the preparation of a specific vaccine and despatched an expert bacteriologist, Dr. Falco, and appointed Dr. Ferran as delegate to study the preparation of vaccines and their application to the sick. At the same time he encouraged the municipal laboratory of Madrid to prepare a vaccine, and all the public health officials there were vaccinated with it. In Valencia, Dr. Ferran and Prof. Peset applied the vaccine, on a large scale, but their tests are not conclusive as the epidemic was already declining at the time. Hence the experiences with vaccine are not adequate to pass any judgment as to the value of preventive vaccination.

IMPORTANCE OF THE EPIDEMIC

It is evident that influenza is one of the gravest scourges that can afflict a country, not only on account of the enormous numbers of persons affected but by the mortality which, although not high in comparison to the numbers attacked, yet is very large considered as a whole. The death rate for those affected was about 3 per thousand but in some places it reached 6 per thousand. The germs encountered were the Pfeiffer bacillus, the pneumococcus and streptococcus.

THE COST OF THE EPIDEMIC

The Public Health Service was put to great expense by the epidemic. It has already paid out 750,000 pesetas and there is much yet to pay. The scarcity of physicians in certain regions and proportionately in others caused many of these places to importune the service for medical aid and an appeal was made for volunteers to go to these points. These volunteers were paid by the government at the rate of 50 pesetas a day, about $10, unless they were being paid already by the municipal authorities. Many physicians succumbed to the epidemic. The total number of deaths from it in the profession is not known yet, but it is over a hundred. The number of the dead and of the disabled will soon be known with precision as the families of the deceased (widows and orphans) have a right to a pension.

FRONTIER SANITARY SERVICE

Dr. Salazar complained that the political powers had never listened to his constant appeals for the reorganization of the sanitary service, but he insisted that, in spite of this, the frontier *servicio sanitario* in Spain is at this very moment of a higher grade than that existing elsewhere, even in France. There are in Spain seven first class *estaciones sanitarias,* two on the French border, at the eastern and western ends, and five on the border of Portugal, with a large number of stations of the second class. Each of the seven first class stations has complete laboratories, animals for experimental research, sterilization plants, etc., and an abundant and select personnel kept abreast with progress by the studies and practical work required of them. Each of the seven stations has its special hospital.

The Outlook for the Public Health Service

The inspector general de sanidad had been urged by friends to take a much needed rest, when recently a man of courage and capacity was appointed ministro de la gobernacion (possibly acting premier) the man who is the hope of the physicians of Spain, Dr. Gimeno, the first physician to be appointed to that cabinet position. The inspector general meets in the new minister a capacity which understands, and he feels the breath of new life; he has recovered his health and energies and turned again with zeal and a smile to renew the battle against disease and ignorance.

MEXICO LETTER

MEXICO CITY, Feb. 9, 1919.

Death Rate Exceeds Birth Rate in the Capital

According to some recently published statistics, there were 21,915 deaths recorded in the city of Mexico during 1918, and only 7,542 births, which seems to indicate that the population has been reduced by 14,373. But this last figure cannot be regarded as accurate because there are always a number of persons who fail to comply with the official regulations for notification in the respective bureaus of the birth of their children. But even making allowance for all this, there is no doubt that the death rate exceeded the birth rate. Influenza was responsible for 1,935 deaths, syphilis for 232, bronchitis for 1,556, bronchopneumonia for 1,456, pneumonia for 2,312, enteritis for 5,496, and various ailments for the other deaths. The high figure of the deaths from pneumonia is remarkable but this is not restricted, I believe, to Mexico.

Is Asiatic Cholera in New York?

Some alarm has been aroused by news received from Vera Cruz to the effect that the papers of a ship arriving from New York specify the existence of Asiatic cholera in that important city of North America. The sanitary authorities have been investigating since then the truth of this rumor.

Bovine Tuberculosis

The Departamento de Salubridad has arranged for a rigorous inspection of cattle imported into Yucatan, as it has been learned that a large number of cows which have been brought into the country by the port of Progreso have been found affected with tuberculosis. A commission of veterinarians has been appointed to take charge of the matter. There had previously been no official inspection of cattle at this port of Progreso, and unscrupulous sellers and purchasers of live stock took advantage of this fact to unload there their sick cattle, with grave injury to the public health.

Typhus

During the last week of January, there were forty-nine cases of tabardillo recorded, and the week following, fifty-eight cases of the same. Tabardillo is endemic here, and it flares up again and again with most distressing periodicity, notwithstanding the measures taken to keep it under control.

Radium

The government of the federal district has acquired an amount of radium valued at $10,000, and it has arranged that the precious metal can be utilized by physicians who wish to apply it in the treatment of cancer, provided that they are adepts in its use. When the patients are poor, the radium will be supplied gratuitously, but those able to pay will be charged a modest rent for the loan of the metal.

Smallpox

This serious disease has appeared in epidemic form in the state of Sinaloa, adjoining Sonora. Numerous cases have been reported.

Inauguration of the University Courses

The courses for the new year were inaugurated the 7th, the rector of the university, Lic. J. N. Macías, presiding.

The formal ceremony was held in the amphitheater of the Escuela Preparatoria. The culminating note of this gathering was the friendly tone employed by two of the speakers in referring to the United States, one of them Dr. Castanedo of the Facultad de Medicina, in speaking of the present situation of the world. The importance of this fact will be understood better when it is realized that until quite recently it was an evidence of patriotism (?) to attack our neighbors to the north, and that sooner or later the influence of the universities will be felt in the formation of the national spirit and in the march of public affairs.

PARIS LETTER

Paris, Jan. 30, 1919.

Management of War Wounds of the Deep Urethra

This question was the subject of an important discussion at the fourth reunion of the chefs de centres génito-urinaires which was held recently. Dr. Heitz-Boyer, chief of the surgical clinic of the Paris medical faculty, maintained that at the front the treatment of lesions of the posterior urethra is determined by the fact whether this is the only wound or whether it is associated with wounds of other viscera and of the bones. When only the urethra is involved, the soft parts must be treated with as much care as the urethra itself. The treatment of the soft parts consists in the excision of contused tissues; immediate suture not being indicated in the majority of cases, especially when the wound is in the gluteal region; secondary suture or delayed primary suture is better here. The treatment of the urethra varies according to the case. If the lesion is not extensive and of recent origin, immediate suture is indicated, with a retention catheter. If the lesions are very extensive and more than forty-eight hours old, the urethral wound should be left open and the urine evacuated, preferably through a suprapubic opening into the bladder; this is particularly indicated in prostatic lesions.

TREATMENT OF ASSOCIATED LESIONS

The treatment of the associated lesions consists in immediate suture of the anus, with the production of temporary constipation. In cases of wounds of the lower segment of the rectum it is only rarely possible to resort to immediate suture; it is best to perform a colostomy at the outset through which the bowel contents can be evacuated. If diversion of the urine is also necessary, this should be done through the perineum. In cases of pelvic cellulitis, excellent drainage may be obtained by resecting the coccyx. If there is present a bladder wound, suprapubic cystostomy is always indicated. Associated bone lesions demand cleaning out the wound very thoroughly, removing all bone fragments, and assuring maximum drainage by interrupted irrigation, preferably with ether. The existence of extensive lesions of the venous channels, especially those of the pelvis, demands evacuation of the hematoma, ligation of the bleeding vessels, if necessary, and free drainage.

OBSTRUCTION OF POSTERIOR URETHRA

Dr. Marion of Paris presented a report in which he drew the following conclusions: In the presence of an obstruction in the posterior urethra, the result of trauma, the two ends of the urethra are caught up, any interposing tissue is dissected out, and the urethral canal is reconstructed by end-to-end suture anastomosis, if possible; if not, by bringing the periurethral tissues into approximation, if urethrorrhaphy is impossible. When a urethrorrhaphy is done, no catheter should be placed in the urethra. If the ends of the divided urethra are separated widely or retracted or contracted, a dilatation should be done, and if this fails, internal urethrotomy should be attempted. If this procedure also fails, then urethroplasty must be done, as in any case of obstruction. Whenever the urethral lesion is complicated by fistula, it is well to make sure at the very outset that the surrounding tissues or areas have been put in the best sanitary condition (cystostomy, opening of abscesses, removing foreign bodies, calculi and sequestra) and then introduce a urethral catheter. This is often sufficient to produce a cure.

URETHRORECTAL FISTULA

In cases of urethrorectal fistula, the urethra is separated from the rectum and then the openings in each canal may be closed in any one of the following ways: (1) Each opening is closed separately and periurethral tissues are interposed between the rectum and urethra; (2) a flap of rectal mucosa is drawn down over the fistulous opening; (3) the rectum is divided above the sphincter, and the upper end is sutured into the anal margin, if there is narrowing of the rectum. Exceptionally, colostomy will have to be done to provide for proper emptying of the bowel. In cases of extensive destruction of the urethra and of the perineal tissues, autoplasty must be resorted to, making use of the scrotal tissues and of the skin of the thigh. When the posterior urethra is completely destroyed, with, perhaps, destruction of the anus, recourse must be had to a cystostomy, and sometimes to perineal urethrostomy with iliac colostomy if the anorectal lesions are irreparable.

FUNCTIONAL DISTURBANCES

Finally, when all these lesions have been repaired, if the patient still has functional disturbances, a periurethral abscess must be thought of, or a persisting foreign body, and the proper treatment instituted. The urethra having been repaired, it is important that the patient be taught the use of a dilator, or that he remain under supervision for a certain time, so as to prevent a narrowing or a deviation of the urethral canal. In order to secure a good view of the posterior urethra, it is desirable to have most ample access. Among the best procedures for exposing this region well, in an appropriate case, is the freeing of the median puboprostatic fascia.

DISCUSSION

Dr. Escat of Marseilles has seen 24 cases of trauma of the pelvic urethra, with accompanying bone lesions in 17 cases, anal or anorectal lesions in 12 cases, lesions of the bladder in 8 cases. By the time these cases reach the base hospitals, chronic infection is present, loss of tissue entailing fistulas and strictures. The trauma usually involves either the prostatic or the membranous urethra.

Dr. Michon of Paris advised that in the less severe or mild cases the treatment at the front should aim to approximate the torn ends of the urethra so as to make easier the surgical intervention which remains to be made at the rear. Suprapubic cystostomy should always be done in these cases because it is an easy means for draining the bladder, and favors constant supervision of the case. He has never found it necessary to perform a colostomy (iliac), and in order to prevent the development of pelvic cellulitis, he prefers to drain the pelvis through the perineum. The prolonged retention of the urethral catheter is not favorable to urethral suture. If it is feared that the subsequent introduction of dilators will be difficult, a conducting thread may be left in the urethra and drawn out through the suprapubic opening. The catheter may be attached to this guide.

Dr. Pasteau of Paris expressed the opinion that at the front in cases of wounds of the deep urethra, the wound should be opened widely, as much as the state of the patient will permit, the region thoroughly explored and provision made for ample and free drainage; the bladder itself should be drained through a suprapubic opening, and likewise any juxta-urethral focus which may have resulted from the trauma or the operation. On the other hand, at the rear, if the posterior urethra has been seriously injured, make a suprapubic cystostomy and drain the perineal region freely; avoid suture of the perineal fascial planes; search for the torn ends of the urethra, place them in apposition, using a retention catheter if necessary. Finally, open widely all the perineal foci and fistulas that may be present, and keep them open, for which purpose the suprapubic cystostomy is helpful. This is the best treatment, preventive and curative, of strictures from lesions of the deep urethra, in which the prognosis is always grave.

Marriages

Lincoln Humphreys, Asst. Surg., Lieut. (j. g.), U. S. Navy, North Little Rock, Ark., to Miss Julia Josephine Youngquist of St. Paul, at Washington, D. C., January 14.

Bret Albert Swartz, Lieut., M. C., U. S. Army, Los Angeles, on duty at Camp Kearny, San Diego, Calif., to Miss Daisy Stegg, also of Los Angeles, January 29.

Edmund Leo Finley, Rochester, N. Y., to Miss Irene Elizabeth Dunn of Rome, N. Y., February 18.

George Millard Dawson to Miss Margarethe Dittrich, both of New York City, February 12.

Deaths

Joseph James Kinyoun ⊕ **Major, M. C., U. S. Army,** Washington, D. C.; Bellevue Hospital Medical College, 1882; aged 58; who entered the U. S. Marine Hospital Service in 1886, and resigned from that service in 1902, with the grade of surgeon; professor of hygiene and bacteriology from 1890 to 1892, and of pathology and bacteriology from 1892 to 1899 in Georgetown University, Washington, D. C.; who on account of eminent sanitary services to the Republic of Venezuela was decorated with the Order of Bolivar in 1897; a member of the Association of American Physicians, Association of American Bacteriologists, and American Public Health Association; for many years bacteriologist of the Health Department of the District of Columbia, and on leave to accept commission in the Army; founder and first director of the United States Hygienic Laboratory; director of the H. K. Mulford Company Laboratories, from 1902 to 1907; on duty in the cantonments of North and South Carolina, until Dec. 6, 1918, when he was detailed as pathologist in the Army Medical Museum, Washington; died at his home, February 14, from lymphosarcoma of the neck.

Richard Ernest Kunze, Phoenix, Ariz.; Eclectic Medical College of the City of New York, 1868; aged 80; a practitioner of New York until 1896, also a doctor of pharmacy, and since that time a student and investigator in medical botany and insect fauna, in Arizona; a specialist in cactus; and an exporter from his cactus farm in Arizona of varieties of cactus to botanical gardens in all parts of the world; at one time president of the New York Therapeutic Society and corresponding secretary of his alma mater; author of many monographs on cactus; died at his home, February 10.

James Williamson Squires ⊕ **Capt., M. C., U. S. Army,** Charlotte, N. C.; North Carolina Medical College, Charlotte, N. C., 1911; aged 30; professor of rectal diseases in his alma mater; a specialist on roentgenology; who entered the service, June 16, 1917, and after serving at Fort Oglethorpe, Ga., and Rockefeller Institute, New York City, sailed for France, in August, 1917, and was on duty with the Yale Hospital Unit, November 30; died in the U. S. General Hospital, Toul, France, Dec. 16, 1918, from lobar pneumonia following influenza.

Aaron Shiner Oberly ⊕ **Capt., Med. Dir. U. S. Navy,** retired, Avon, Conn.; Yale University, New Haven, Conn., 1860; aged 81; who entered the navy, July 1, 1861; serving throughout the Civil War; was chief surgeon of the Adriatic Squadron, in 1886; and was retired after ten years and eleven months' sea service, Jan. 4, 1889, with the next higher grade to that held on the active list, on account of incapacity resulting from an incident of service; died at his home, February 15.

John Alfred Bodine ⊕ New York City; University of Louisville, Ky., 1893; aged 53; professor of surgery in the New York Polyclinic Medical School; attending surgeon to St. Johns Hospital, Long Island City, and to the Northwestern and Northern Dispensaries; a specialist in surgery; visiting surgeon to the Polyclinic Hospital; a fellow of the New York Academy of Medicine; dropped dead from heart disease in the New York Athletic Club, February 24.

Bedford Wagoner Russell ⊕ **Lieut., M. C., U. S. Army,** Strong City, Okla.; Epworth College of Medicine, Oklahoma City, Okla., 1909; aged 31; who had been on duty at Fort Riley, Kan., and was ordered to the U. S. Army General Hospital, Fort Des Moines, Iowa, for observation and treatment, January 3; and was discharged from the service, February 6; died at the home of his mother in Oklahoma City, February 13, from the effects of influenza.

Died in the Service
in North Russia
Lieut. Ralph E. Powers, M. C.,
U. S. Army, 1890-1919

Elton Bane Rogers ⊕ **Capt., M. C., U. S. Army,** Winchester, Idaho; Northwestern University Medical School, Chicago, 1907; aged 38; who after entering the service, was sent to the University Hospital, Philadelphia, for instruction, later to Camp Dix, N. J., and then on to Hoboken, N. J., May 25, 1918, for overseas duty; formerly local surgeon of the Milwaukee system at Dear Lodge, Mont.; died recently in France.

Elijah Stephens Kelley, Minneapolis; Rush Medical College, 1878; aged 72; at one time a member of the Minnesota State Medical Association; for four years health commissioner of Minneapolis; for one term police surgeon, and once physician of Hennepin County; died at his home, February 6, from influenza.

Andrew Aloysius Conlon, Chicago; Bellevue Hospital Medical College, 1885; aged 57; at one time a member of the Illinois State Medical Society; for nineteen years a member of the medical staff of the Chicago Department of Health; died at his home, February 19, from chronic parenchymatous nephritis.

Charles Newell Palmer, Lockport, N. Y.; New York University, New York City, 1865; aged 77; attending physician to the Lockport Tuberculosis Dispensary, and consulting physician to the Sister's Hospital, Buffalo; a member of the Medical Society of the State of New York; died, February 3.

Harold William Brown ⊕ **Lieut., M. C., U. S. Army,** Jersey City, N. J.; Cornell University, New York City, 1908; aged 32; on duty at Camp Leach, Washington, D. C., was found dead Nov. 3, 1918, from asphyxia, due to chloroform inhalation, self-administered, while in a state of melancholia.

Azariah Kinyon Jewell, Columbus, Ohio; Detroit College of Medicine and Surgery, 1905; aged 40; at one time a member of the Ohio State Medical Association, and local surgeon of the Cincinnati, Hamilton and Dayton Railroad; died at his home, January 9, from pneumonia following influenza.

Daniel Avery Langworthy, Minneapolis; College of Physicians and Surgeons in the City of New York, 1860; aged 87; captain of the 85th New York Volunteer Infantry during the Civil War; a pioneer lumber dealer of North Dakota; died at his home, January 14, from cerebral hemorrhage.

John Irwin Warder ⊕ Weston, W. Va., University of Maryland, Baltimore, 1879; aged 62; president of the Lewis County Medical Society; for three terms mayor of Weston, and once a member of the legislature from Lewis County; died at his home, February 9, from heart disease.

Ralph Edgar Powers ⊕ **Lieut., M. C., U. S. Army,** Akron, Ohio; Eclectic Medical Institute, Cincinnati, 1915; aged 28; on duty with the American Expeditionary Forces in North Russia, and senior medical officer of the 337th Ambulance Company, 339th Infantry; died, January 22, from wounds received in action.

John Alexander Lyons ⊕ Chicago; Long Island College Hospital, Brooklyn, 1889; aged 65; a member of the American Association of Obstetricians and Gynecologists; surgeon and gynecologist to the Chicago Hospital; died at his home, February 18, after an operation for appendicitis.

William B. Callender, Stockton, Kan.; Drake University, Des Moines, Iowa, 1887; aged 63; at one time a member of the Kansas Medical Society; for twenty-six years local surgeon for the Missouri Pacific system; died in the Concordia (Kan.) Hospital, February 5.

George Heman Sadelson, Charlotte, N. C.; University of Buffalo, N. Y., 1876; aged 64; a member of the Medical Society of the State of North Carolina; a specialist on dermatology and tuberculosis; died at his home, February 10, from influenza.

Henry Nollner Rosser, Birmingham, Ala.; Emory University, Atlanta, Ga., 1869; aged 76; a member of the Medical Association of the State of Alabama; for eight years health officer of Jefferson County; died at his home, January 24.

⊕ Indicates "Fellow" of the American Medical Association.

Willis Henry Maxson, Oakland, Calif.; University of Michigan, Ann Arbor, 1883; aged 63; at one time a member of the Medical Society of the State of California; died in a sanitarium in Berkeley, Calif., February 4, from heart disease.

Levi Hornor ⊕ Wichita, Kan.; Kansas City (Mo.) Medical College, 1886; aged 62; for several years physician of Sedgwick County and a member of the local board of education; died in a drug store in Wichita, February 6, from heart disease.

Charles Nicholas Van Denberge, Philadelphia; Albany (N. Y.) Medical College, 1897; aged 41; at one time a member of the Medical Society of the State of New York; died in Philadelphia, January 22, from acute pyonephritis.

Charles Orth, Rock Creek, Ohio., formerly of Pittsburgh (license, Allegheny County, Pa., 1881); aged 99; surgeon of U. S. Volunteers throughout the Civil War; died at the home of his son, in Rock Creek, January 29.

Earl Lawrence Uhl ⊕ Baldwin City, Kan.; Rush Medical College, 1911; aged 33; a specialist on diseases of the ear, nose and throat; died at his home, February 10, from empyema following pneumonia.

William E. Poulton, Washington, D. C.; Georgetown University, Washington, D. C., 1864; aged 79; a member of the Medical Society of the District of Columbia; died at the home of his son, February 14.

Edward Sartor Stewart ⊕ **Lieut., M. C., U. S. Army,** Summertown, Tenn.; Vanderbilt University, Nashville, Tenn., 1911; aged 32; died at Camp Greenleaf, Ga., Oct. 19, 1918, from left lobular pneumonia.

Julian Rush Sutton ⊕ Black Mountain, N. C.; University of the South, Sewanee, Tenn., 1904; aged 38; died in the Mission Hospital, Asheville, N. C., Oct. 30, 1918, from pneumonia following influenza.

Guy Clayton Bowe, Cleveland; Northwestern University Medical School, Chicago, 1895; aged 49; a member of the Ohio State Medical Association; died at his home, February 5, from pneumonia.

Samuel H. Robertson, Crisfield, Md.; University of Maryland, Baltimore, 1853; aged 85; for several years superintendent of the public schools of Somerset County; died at his home, February 21.

John S. Rome, Los Angeles; University of Michigan, Ann Arbor, 1866; aged 78; formerly a resident of Calmar, Iowa, and a member of the Iowa state legislature; died at his home, about February 5.

Herbert Lawson Williams, Pittsburgh, Pa.; University of Pittsburgh, 1918; aged 24; died in the Ohio Valley General Hospital, Pittsburgh, February 3, from the effects of a gunshot wound.

John M. West; Red Bluff, Calif.; Rush Medical College, 1864; aged 82; formerly a member of the Medical Society of the State of California; died in Red Bluffs, Calif., February 10.

John D. Hess ⊕ **Capt., M. C., U. S. Army,** Clarkton, Mo.; Washington University, St. Louis, 1900; aged 41; on duty at Fort Bliss, Texas; died, Oct. 17, 1918, from pneumonia.

James Wiltse ⊕ Brewster, N. Y.; Bellevue Hospital Medical College, 1890; aged 54; health officer of Putnam County; died at his home, February 2, from lobar pneumonia.

Andrew B. Lennington ⊕ Maybee, Mich.; Detroit College of Medicine and Surgery, 1900; aged 51; died suddenly at his home, February 6, from intestinal obstruction.

John Awvill Pennington ⊕ **Lieut., M. C., U. S. Army,** New York City; University of Tennessee, Nashville, 1918; aged 26; died, October 4, 1918, from influenza.

Jay Amherst Latimer ⊕ Claremont, Calif., Cleveland College of Physicians and Surgeons, 1898; aged 44; died at his home, January 24, from pneumonia.

Mary Henrietta Rowland, Davenport, Ia.; Hahnemann Medical College, 1866; aged 68; died at her home, February 7, from nephritis.

Luman L. Wescott, Chicago; Chicago Homeopathic Medical College, 1898; aged 52; died at his home, February 11, from arteriosclerosis.

Henry W. Shirley ⊕ Shoals, Ind.; Medical College of Ohio, Cincinnati, 1878; aged 76; died at his home, January 28, from angina pectoris.

Solomon W. Biddinger, Hartsville, Ind. (license, Indiana, 1897); aged 85; a practitioner since 1857; died at his home, about February 6.

The Propaganda for Reform

In This Department Appear Reports of the Council on Pharmacy and Chemistry and of the Association Laboratory, Together with Other Matter Tending to Aid Intelligent Prescribing and to Oppose Medical Fraud on the Public and on the Profession

PHARMACEUTICAL MANUFACTURERS AND "PRIVATE FORMULA" PRODUCTS

To the Editor:—American makers of pharmaceuticals have for many years considered it commercially ethical to make legitimate pharmacal products according to so-called, "Private Formulæ" submitted for manufacture by reputable physicians and druggists for their own dispensing. To do otherwise would be an untenable refusal on the part of the manufacturer to serve the interests and supply the needs of a rather large clientele through his laboratory. Logically in these transactions the manufacturer's obligations begin and end with the correct manufacture of the product and the use of the materials specified by the patron. To hold the manufacturer even remotely responsible for the ultimate dispensing or distribution of such products manifestly would be an impossible requirement.

Our inflexible rule is that all such "Private Formulæ" orders as are evidently intended for public distribution and not for personal dispensing by physicians or druggists, are positively refused acceptance until the "copy" for the "literature" has been critically studied by experts on our New York office staff. This is particularly true of all such orders coming from Spanish-speaking countries where it appears to be the fact that misrepresentations and exaggerations in such "literature" are not so critically censored as in the U. S. A.

The head of our Spanish Export Department personally censors all such "copy"; in his absence this is done with equal care by his first assistant. Naturally we must depend on the loyalty and integrity of these business associates for a correct translation into English and a rigid censorship of all such "copy" since we ourselves are not intimately familiar with Spanish. Probably at the present time, now that you are issuing a Spanish edition of The Journal, your own dependence on Spanish-speaking colleagues for ethical accuracy and the avoidance of error is keenly appreciated by the editorial staff of The Journal.

We have never knowingly accepted or filled an order for a product the ultimate disposition of which was to be accomplished through misrepresentation or fraud. For years we have had two druggist patrons in Arecibo, Porto Rico—both men of good repute; both patrons submitted orders for "Private Formulæ" products in 1915. Three such products were ordered; each order was accompanied by "copy" in Spanish to be used by us for them on the labels and circulars.

The head of our Spanish Export Department was away on a commercial trip in Latin-America when these orders arrived in New York. His first assistant was temporarily ill. His second assistant, a Spanish-speaking man, took the responsibility of passing on this "copy" and he O.K.'d it as being correct and in compliance with our rigid rules as to accuracy of statement and these orders with these pieces of "copy" in Spanish were sent by him to our Private Formula Department at Baltimore. The superintendent of that department at Baltimore, knowing nothing of the absence from New York of the head of the Spanish Export Department and therefore naturally assuming that these pieces of Spanish "copy" had been properly censored, accepted these orders in good faith.

The goods were made up, labeled with the Spanish "copy" and were shipped to our Porto Rican patrons. On their arrival in Porto Rico they were inspected by American experts and these inspectors at once determined from the printed matter on and around the packages that the products were "misbranded" and in due time, we, as the manufacturers, were notified to that effect. The moment we saw for the first time an accurate translation of the Spanish "copy" we recognized the fact that we had been misled by our Spanish office assistant and promptly discharged him for the offense.

To facilitate the removal of the cases from the docket and at the urgent solicitation of our attorney and with the concurrence of the court we paid the nominal fine in each case, which later on was refunded to us by the customer. At the same time we notified these two patrons that we insisted on their withdrawing the three products from the market until every package was redressed with new labels and circulars in the wording of which none but true statements were to appear. It is to the credit of both men to say that both cheerfully acquiesced and both had every package redressed properly before a single package was offered for sale.

Our reason for inflicting this lengthy communication on your readers is that through the publication in Volume 72 of The Journal (see page 60, Jan. 4, 1919) Sharp & Dohme is by inference held out as being *particeps criminis* and as the originators and promoters of these three undoubtedly "Misbranded Nostrums." The injustice of that inference must appeal at once to all fair-minded men who through reading the foregoing statement of absolute facts must concede that we were and are innocent of any intentional cooperation with this "misbranding."

Therefore it is with a keen appreciation of your fairness to all houses of good repute that we ask that you give this communication a place in the widely read Journal, thereby affording us an opportunity of putting ourselves in the right light before the large group of ethical physicians whom we have honestly served for so many years and whose respect and confidence we feel that we can justly expect to retain.

Sharp & Dohme.

P. S.—The subjoined imprint appears on every invoice of "Private Formulæ" preparations:

> "We hereby guarantee that the Private Formula preparation here invoiced was made according to the formula furnished to us. It is mutually agreed that we are not responsible for its disposition nor for any claimed medicinal action.—Sharp & Dohme."

[Comment.—The letter above is published because the house of Sharp & Dohme, as a reputable business concern, feels that it has been done an injustice by the publication of three brief items, abstracted from federal reports. These reports, of course, gave no hints of the fact that these preparations were "private formula" products. The Journal is willing to admit that there was a possible injustice done Sharp & Dohme in that its readers would naturally infer that these three misbranded "patent medicines" were *sold under the name of* Sharp & Dohme, instead of *being made by* Sharp & Dohme, to be sold by some one else. There is, unfortunately, a commercial distinction between these two facts; whether or not there is any moral difference between profiting by the manufacture of a "patent medicine" that is to be retailed by somebody else, and selling the same medicine under one's own name, is a question that may safely be left to the medical profession to answer.—Ed.]

MORE MISBRANDED NOSTRUMS

Alkavis.—Shipped, June, 1915, by M. Agnes Jamieson, trading as the Alkavis Co., Detroit. Analysis showed the preparation to be essentially a solution containing potassium nitrate, sodium benzoate, glycerin, and vegetable extractives. Falsely and fraudulently represented as a remedy for diseases of the kidneys, liver and urinary organs. Fine, $50.—[*Notice of Judgment No. 5247.*]

Sulferro-Sol.—Shipped in November, 1917, by the Sul-Ferro-Sol Co., Inc., Birmingham, Ala. Falsely and fraudulently represented as a remedy for pellagra, kidney and bladder trouble, rheumatism, tuberculosis of the bone, etc. Court entered judgment of condemnation and forfeiture and ordered that the product be destroyed.—[*Notice of Judgment No. 6087.*]

"Gonorrhea and Gleet 3 Day Cure"; "Old Indian Fever Tonic"; "Pain-I-Cure"; and "Walker's Dead Shot Colic Cure."—Shipped in February, 1916, by the Walker Co., Atlanta, Ga. The "Gonorrhea and Gleet 3 Day Cure," when analyzed, appeared to be a solution of zinc sulphate and sulphocarbolate, boric acid, opium and hydrastin. The "Old Indian Fever Tonic" appeared to be a solution of Epsom salt and quinin sulphate, acidified with aromatic sulphuric acid, and colored red with coal tar dye. "Pain-I-Cure" contained over 74 per cent. of alcohol with morphin, red pepper, camphor, and oils of sassafras and cloves. "Walker's Dead Shot Colic Cure" contained over 77 per cent. of alcohol with essential oil, asafetida, guaiac, morphin, camphor, and red pepper. All four products falsely and fraudulently represented. Fine, $50 and costs.—[*Notice of Judgment No. 5781.*]

Correspondence

POSTINFLUENZAL DISTURBANCES OF THE NERVOUS SYSTEM

To the Editor:—Postinfluenzal diseases of the cerebrospinal axis are of common occurrence. They followed in the wake of the last great epidemic and were well described at that time. That there can be a primary invasion of the nervous system, the general signs of an infection being secondarily determined, does not seem from recent observations of mine to be sufficiently kept in mind. In the last two months I have seen in consultation or have had referred to me patients who presented syndromes which at first did not seem to have any connection with our present epidemic: 1. They had not been preceded by bronchial or respiratory symptoms or by temperature elevation. 2. Most of these patients, however, complained of neuralgic pains, headaches or drowsiness almost from the beginning. 3. A slight increase of the body temperature, accompanied as a rule by no rise of the pulse rate, by a low blood pressure and by the characteristic inertia of mind, has followed the paralyses, etc. These general signs have been observed as a rule on about the fourth or fifth day of the disease. 4. A lymphocytosis of the cerebrospinal fluid has been invariably reported. This has varied from 22 cells (paralytic chorea syndrome) to 192 cells (general paresis syndrome). 5. All patients have had a fairly acute onset and recovery has been the rule.

I wish to record briefly certain instructive observations:

One patient presented himself with pronounced twitchings and fibrillary tremor, bleating speech, Argyll Robertson pupil and a dementia. The onset was acute. There was no ethical deficit as in true paresis, however. Nor was there the ever-present erethism or depression of the true paralytic dementia. Two days after I first saw this patient, a rise in temperature was observed and the ordinary influenza symptoms came on. In two weeks, he commenced to recover. His memory returned, his tremors subsided, his speech bettered itself, and his eyes reacted again to light. It was in this patient that a lymphocytosis of 192 was reported.

The frequency of encephalitis unaccompanied by frank meningitic symptoms has been reported before. Multiple cranial palsies without a previous history of infection have been observed by me in five consultations during the last two months. In no case were bulbar symptoms present. Their onset was acute. A diplopia seems to have preceded all other symptoms. The uniform recovery in these cases excludes a hemorrhagic type of encephalitis and would indicate a toxic basis. All the patients were apathetic, inert and dull for the several weeks it took the paralyses to clear up. Two of them developed a fever with a drop of blood pressure a few days after the initial paralysis. All had a lymphocytosis. In one case, Pfeiffer's bacillus was reported on culture. The symptoms varied somewhat, but included ptosis of the eyelid, diplopias of various types, facial paralysis, and brachial paresis. All the patients had a miosis, a failure of the accommodation reflex, and an almost absent pupillary light reaction. Absent reflexes on one or both sides of the body were noted. I imagine that transient diplopias must have been very common from conversations with various general practitioners. Ophthalmoplegia after or during infections is, of course, a commonplace. At present these toxic ophthalmoplegias and diplegias are occurring in too large a number not to be significant in connection with the present epidemic.

I have noticed also an unusual number of unilateral choreas this winter with pronounced paralytic symptoms. Have they any connection with influenza? I have not been able to study them from the laboratory standpoint to have an opinion.

I was confused in two cases by a close similarity in symptoms to cerebrospinal syphilis. Mental dulness, with a facial diplegia or a brachial monoplegia and oculomotor paralyses, accompanied by a lymphocytosis, does not always represent a syphilitic picture. The difference lies in the absence of a premonitory period, the comparative absence of a general breakdown preceding the onset of the palsies, and the early and pronounced mental dulness. The palsies were not so fugacious as in true cerebrospinal syphilis and disappeared more progressively; and, of course, the Wassermann and colloidal gold tests are always negative, despite the increased lymphocytosis. Both patients had an accommodation spasm with miosis.

Edward E. Mayer, M.D., Pittsburgh.

"OHIO FINDS A BETTER WAY"

To the Editor:—Allow me to congratulate you on the stand you take in endorsing the action of the Ohio State Medical Association on throwing the responsibility of public health on the legislature by not opposing bills licensing certain cults and sects.

During the last thirty years while going to the legislature opposing bills of the osteopaths, Christian scientists and the like, I came to the conclusion that the best way to deal with them is to ignore them.

L. W. Zwisohn, M.D., New York.

A PROTEST AGAINST THE SENDING SOUTH OF INDIGENT TUBERCULOSIS PATIENTS

To the Editor:—May I protest against physicians in other parts of the country telling indigent tuberculous patients to go South for the winter? For the past few years, an average of thirty transient tuberculous people have died each year in our community. We have no proper place as yet to care for our own tuberculous, and the migratory consumptive adds greatly to our problem. Plans are under way for a county sanatorium at Jacksonville. There is no state institution and at present no private institution in Florida for the care of tuberculosis.

William W. MacDonell, M.D., Jacksonville, Fla.
City Health Officer.

THE SUPPLY OF PRACTICAL NURSES

To the Editor:—Since the necessity of presenting a nursing bill at the present session of the Illinois legislature became known, an honest effort has been made to try to remove some of the nursing difficulties of the state. To help overcome the shortage of nurses, the course of thirty-six months for the registered nurse has been cut down in a proposed bill to a minimum of twenty-seven months, and a course of eighteen months established for a new group, this also to be registered.

To assure the eighteen months' nurse being kept for the bedside care of the sick, a restriction preventing her doing public health work, acting as a supervisor, instructor or executive, has been made. This seems worth trying, as one great cause of the shortage of the private duty nurse is her absorption into other forms of nursing.

The need of a part nurse, part housekeeper in the home is fully appreciated, but it seemed unwise to incorporate in a possible law a type that had not yet been successfully developed. Long observation seems to show that most private duty nurses, after the first enthusiasm wears away, either are unwilling to do household duties or get discouraged and give up private duty. The advice of the women at the head of the homes would be valuable as to the practicability of one woman continuously nursing the sick and caring for the home at the same time.

It seemed equally unsound to introduce into a law the experimental short course nurse, with the fear of sending into the field many but poor nurses; and out of consideration for the hospitals whose sick need equal consideration, eighteen months as the shortest period was finally settled on.

The effort of carrying a registered nurses' school has undoubtedly become burdensome to some hospitals, and it is unjust that those institutions should have to carry heavy educational problems in addition to their many responsibilities or be considered not accredited. It has been thought that with the two groups of women, hospitals might decide which type of school they wished to conduct—the registered nurse school with the expense of many instructors and equipment, or junior registered nurse school, equally dignified and important, giving in eighteen months an intensive instruction to qualify for good bedside nursing care, having class instruction in practical nursing, invalid cooking, personal and home hygiene, and possibly a little anatomy and physiology.

The name of Junior Registered Nurse was not given in a feeling of patronage or to indicate inferiority either for the school or for the woman. It is usually granted that a twenty-seven months' course is more advanced than an eighteen months' period, and it is in this sense alone that the term was applied. The words Junior Registered Nurse also indicate that, should the woman care to, she may at some time qualify for Registered Nurse. Neither the Registered Nurse nor the Junior Registered Nurse will carry the title Registered around with her, and both will be called nurse. Restrictive clauses specifying those who may nurse for hire will make it a mandatory law if passed.

While most nurses advise against an entrance age under 21, practical reasons and public demand have placed the age at 19. It has been thought that in this age of general education one year high school entrance has not been too much to ask.

The other points of the bill deal with administration. The majority of the registered nurses in Illinois have endorsed this bill as a possible solution of a difficult situation. It cannot be attempted or successfully worked out without the cooperation of every interested person, the medical profession to understand and interpret it to the community, the nurses realizing the opportunity to perform a valuable service by developing and welcoming this second group of registered nurses and the department of the state, under which the schools will be administered, exercising a just control.

M. H. McMillan, Presbyterian Hospital, Chicago.
President, Illinois State Association of Graduate Nurses.

[Dr. M. L. Harris, representing the Illinois Hospital Association, comments:]

To the Editor:—The people have long experienced difficulty in securing nurses who are willing to wait on the sick, and the seriousness of the situation was greatly accentuated during the recent epidemic. Not only is there a shortage of nurses, but there is a growing tendency on the part of the registered nurse to escape doing private duty or actual nursing. Both of these facts have been recognized by the people, who are demanding that something be done to remedy the situation.

The nurses' organization recently introduced into the legislature of Illinois a nursing bill which they believe to be "an honest effort to try to remove some of the nursing difficulties of the state." If its proposed bill will remove the existing difficulties and enable the sick to secure some one to wait on them during their illness, it is a good bill; but, if it does not remove the difficulties, then some bill should be substituted for it which will.

Referring to its bill, it is casually remarked in the preceding letter that "restrictive clauses specifying those who may nurse for *hire* will make it a mandatory law if passed." The first paragraph of the proposed law provides that it shall be unlawful for any person to nurse the sick who is not a registered nurse or a junior registered nurse. The question of "hire" does not enter into [illegible] A person [illegible]ld not render even gra[illegible] [illegible]e sick; no[illegible] [illegible]y that, but the bill [illegible] brothers of religious organizations that conduct hospitals from nursing the sick either in their hospitals or in the patients' homes, and would likewise exclude from nursing all male nurses and all unregistered nurses, even though graduates, unless they chose to register—and many of them do not so elect—and all practical nurses, however great the necessity for their existence may be, and however great the good that they may do.

The number of sick persons well cared for every day by these large groups amounts to thousands. Under the proposed bill, it would be imposible for these suffering sick to obtain any one to take care of them, either for hire or as a gratuitous service, unless they were able to secure the services of a registered nurse. Unfortunately there are not enough registered nurses to meet the demand; hence under the proposed law at least nine out of ten of the sick would be compelled to be without a nurse's care, except such as might be rendered them by members of the family.

Could a law that would make it impossible for a sick person to secure some one to wait on him during his illness be considered anything but inhuman? It is proposed to help this situation by establishing a new group of nurses to be given an eighteen months' course of training, and to be known as Junior Registered Nurses.

These Junior Nurses are to be the real nurses of the sick. They are to do all the actual work, while the registered nurse is to do all the supervising. Note the wording of the letter: "To *assure* the eighteen months' nurse being *kept* for the bedside care of the sick," the law is to prevent her from doing anything else. Under the proposed bill the registered nurse is permitted to do all the supervising and executive work, all the teaching and instructing, all the institutional work, and all the public health work; in other words, all the supervising, while the Junior Nurse is made to do all the waiting on the sick. The bill reads as follows: "A Junior registered nurse may nurse the sick or disabled, but may neither engage in public health nursing, act in a supervisory capacity, in a hospital or similar institution, act as an instructor or in a supervisory capacity in a school of nursing, nor act as an instructor or in a supervisory capacity in public health service or any other like service." Moreover, she is not permitted to nurse in a hospital except "when under the immediate personal supervision of registered nurses."

The slave was chained to the galley for life, but that was centuries ago. Can it be that we are returning to that age? Is it possible that the law is to be invoked to create class, to keep a person to a particular work, and to prevent the person from doing anything else? No matter what the Junior Nurse's ambitions may be, no matter what her ability as a teacher, as an instructor, as a supervisor or as an executive, may be; no matter what her aptitude for public health service may be, she is to be prohibited by law to do any of these things or any other similar things.

What evidence is there that "the effort of carrying a registered nurse school has undoubtedly become burdensome to some hospitals"? The hospitals own and maintain practically all of the training schools. Hospitals are conducted for the welfare of the sick, and nursing is essential to their welfare. It is desirable that the expense connected with the care of the sick should be maintained at the lowest point consistent with the highest type of service. A training school in connection with a hospital is the most economical way of providing the best nursing for the sick; then why should hospitals wish to give up their training schools when they know that the expense of caring for their sick would thereby be greatly increased? There is no objection to any hospital prescribing its own qualifications and giving courses of any length which it may desire in order to produce the highest type of instructors, public health and social service workers, and the like; but the people demand and must have some one to care for them when they are sick, and the hospitals, through their training schools, must supply the demand.

True, the preceding letter states that "the words Junior Registered Nurse also indicate that should the woman care to, she may at some time qualify for registered nurse." The words are the only thing that indicate it, for the law makes no provision for her ever becoming anything but a Junior Nurse. That the present day registered nurse is not waiting on the sick is shown by the statement that "one great cause of the shortage of the private duty nurse is her absorption into other forms of nursing." What are "these other forms of nursing"? Institutional work, supervising the work of others, public health work, social service work, etc., most of which are not forms of nursing at all. Not that this line of work is not most valuable and important, for it is, and should be encouraged and extended; but if the registered nurse does not care to wait on the sick, let us have some one who does. Because the registered nurse does not care to nurse the sick, she has no right to say that others who wish to shall not nurse, nor has she any right to say that that nursing shall be dōne only under her supervision.

If the present day system of training the registered nurse is unfitting her for private duty nursing, then there is something wrong with the system, or something wrong with the individuals doing the training. No one familiar with the subject will attempt for a minute to deny that there is a large field for the well trained, well educated specialist in nursing; nor would any one think of restricting or hindering the progress and development of those who are interested in this line of work; but what the great mass of people need and demand is a nurse who will wait on them when they are sick, and who will carry out the orders of their physician.

The proposed bill which the Nurses' Association has presented not only does not supply this great need, but it deprives the people of much of the service along this line which they now have.

M. L. Harris, M.D., Chicago.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

"ROACHES IN A SANATORIUM"

To the Editor:—Referring to a recent query (The Journal, Feb. 15, 1919, p. 515) as to the best method of exterminating roaches in a sanatorium, it has been my experience that the *one* best method for ridding an institution of these insect pests is the careful shutting off of their food supply.

All material that might serve as food for hungry roaches should be kept in tins or insect-proof boxes with properly adjusted and tightly fitting covers. When ventilation is necessary for the preservation of foodstuff, covers should be made of wire gauze with moderately fine mesh. No food scraps of any kind should be allowed to lie around after meals, but should be promptly deposited in a metal-covered garbage can.

This is the first and most important step in ridding a badly infested building of cockroaches, and unless it is properly attended to, the use of roach poison frequently does not result in the extermination of roaches.

L. D. Fricks, M.D., Louisville, Ky.

Surgeon, U. S. P. H. S., Medical Officer in Charge, Camp Zachary Taylor, Civil Sanitary District.

LIMIT OF TAXATION OF OFFICERS' INCOMES

To the Editor:—Please inform me whether or not an officer of the Medical Reserve Corps who has no income other than from the government pay for services is subject to an income tax; that is, is pay from the United States government subject to income tax, or is it exempt?

C. H. Otken, M.D., McComb, Miss.

Answer.—As indicated under Item 1, Heading III, page 1, of instructions on income tax returns, "Pay not exceeding $3,500 for active service in the Military and Naval Service of the United States" is exempt from income tax. This applies to 1918 income only. According to this exemption, physicians in active service in the Army and Navy need not pay income tax on their salaries unless the amount of the salary for 1918 was more than $3,500.

PENDING LEGISLATION FOR EXTRA PAY

To the Editor:—Has a bill been passed by Congress authorizing the payment of one month's extra salary to officers or men honorably discharged from the Army or Navy? Please omit my name. M. W. R.

Answer.—Such a bill has not been passed, although provisions for extra pay are included in pending legislation.

COMING EXAMINATIONS

Alaska: Juneau, March 4. Sec., Dr. L. P. Dawes, Juneau.

Arizona: Phoenix, April 1. Sec., Dr. Allen H. Williams, 219 Goodrich Bldg., Phoenix.

California: Los Angeles, March 17-20. Sec., Dr. C. B. Pinkham, State Capitol, Sacramento.

Colorado: Denver, April 1. Sec., Dr. David A. Strickler, 612 Empire Bldg., Denver.

Connecticut: New Haven, March 11-12. Sec. Reg. Bd., Dr. Chas. A. Tuttle, 196 York St., New Haven; Sec. Eclectic Bd., Dr. J. L. Hair, 730 State St., Bridgeport, and Sec. Homeo. Bd., Dr. E. C. M. Hall, 82 Grand Ave., New Haven

District of Columbia: Washington, April 9-11. Sec., Dr. Edgar P. Copeland, The Rockingham, Washington.

Idaho: Pocatello, April 1-2. Sec., Dr. Ray H. Fisher, Rigby.

Illinois: Chicago, March 3-5. Mr. F. C. Dodds, Supt. of Registration, Springfield.

Iowa: Iowa City, March 24-26. Sec., Dr. G. H. Sumner, Capitol Bldg., Des Moines.

Maine: Portland, March 11-12. Sec., Dr. Frank W. Searle, 776 Congress St., Portland.

Massachusetts: Boston, March 11-13. Sec., Dr. W. P. Bowers, Rm. 501, No. 1 Beacon St., Boston.

Minnesota: Minneapolis, April 1-4. Sec., Dr. T. S. McDavitt, 741 Lowry Bldg., St. Paul.

Montana: Helena, April 1. Sec., Dr. S. A. Cooney, 205 Power Bldg., Helena.

National Board of Medical Examiners: Philadelphia, June 2-7. Sec., Dr. J. S. Rodman, 1310 Medical Arts Bldg., Philadelphia.

New Hampshire: Concord, March 13-14. Sec., Dr. Charles Duncan, Concord.

New Mexico: Sante Fe, April 14-15. Sec., Dr. W. E. Kaser, East Las Vegas.

Oklahoma: Oklahoma City, April 8-9. Sec., Dr. J. J. Williams, Weatherford.

Rhode Island: Providence, April 3-4. Sec., Dr. B. U. Richards, State House, Providence.

Utah: Salt Lake City, April 7-8. Sec., Dr. G. F. Harding, Templeton Bldg., Salt Lake City.

Book Notices

United States Army X-Ray Manual. Authorized by the Surgeon-General of the Army. Prepared under the Direction of the Division of Roentgenology. Leather. Price, $4 net. Pp. 506, with 219 illustrations. New York: Paul B. Hoeber, 1918.

Although written to satisfy military requirements, this manual is a rich epitome of roentgenology. For civil purposes there would have been less space devoted to projectile localization, but otherwise the rudiments of the subject are set forth in well-balanced and masterful style. The contents represent the combined work of several of America's most competent roentgen workers, who aimed to furnish the most valuable handbook for military roentgenologists in the making. Their manual will outlast its purpose because it is almost of equal use as a handbook in civil work and has been made available to the civil public.

Les plaies de guerre et leurs complications immediates. Leçons faites a l'Hotel-Dieu. Par Henri Hartmann, Professeur de Clinique Chirurgicale. Paper. Price 8 francs. Pp. 200, with 58 illustrations. Paris: Masson et Cie, 1918.

This volume consists of a series of eighteen lectures, given by the author at l'Hotel Dieu during the winter semester of 1916 and 1917, in which he endeavored to present as briefly as possible the experiences gained during three years of war. In discussing bullet wounds in general the author states that there is no question that the enemy used explosive bullets; but he does not believe that they were frequently used—not that there were humanitarian reasons but because the explosive bullet does not travel so fast or so far as the full jacketed bullet. In the treatment of war wounds, at least those made by shrapnel, shells, etc., the general principle seems to be fairly well established that the wound should be operated on as soon as possible and all foreign bodies, including tissue débris and the walls of the tract, should be removed, leaving only clean, healthy surfaces, which should be brought together at once in the hope of securing primary union. If this method of treating wounds is thoroughly carried out early, that is, during the first few hours, before infection has well started, the majority of the wounds will heal without suppuration. Even in the case of fractures and wounds of the large joints, this line of treatment may be carried out successfully in a majority of the cases. If infection has already set in, this method of treatment, of course, should not be carried out, so far as the primary closing of the wound is concerned. In discussing shock, the author is inclined to accept Crile's theory. The excellent work done by American investigators at the front on this subject, of course, was not available at the time these lectures were given. The question of the treatment of wounds of the abdomen is still a subject of much discussion. The unavoidable incidental conditions of warfare are so important in this connection that they are largely the determining factor in deciding as to the desirability or not of operating in a given case. The lectures are interesting and instructive in showing what the French surgeons were able to accomplish during the war.

Information for the Tuberculous. By F. W. Wittich, A.M., M.D., Instructor in Medicine and Physician in Charge Tuberculosis Dispensary, University of Minnesota Medical School. Cloth. Price, $1. Pp. 150. St. Louis: C. V. Mosby Company, 1918.

Dr. Wittich's book is an elaboration of the weekly talks given by the author to patients in tuberculosis sanatoriums and is an effort to answer the questions asked by patients on first learning that they are tuberculous and during treatment for their disease. The fact that the author was himself at one time a patient at Saranac Lake gives him an opportunity of recording his experience both as a patient and as a physician. The advice and information given are in keeping with the best developments of sanatorium treatment.

Applied Bacteriology. Studies and Reviews of Some Present-Day Problems for the Laboratory Worker, the Clinician, and the Administrator. Edited by C. H. Browning, M.D., D.P.H., Director of the Bland-Sutton Institute of Pathology, the Middlesex Hospital. Contributors: C. H. Browning, W. Gilmour, R. Gulbransen, T. J. Mackie, S. Russ, J. F. Smith and L. H. D. Thornton. Cloth. Price $2.50. Pp 291, with 4 illustrations. New York: Oxford University Press, 1918.

This book deals with the diagnosis of enteric infections, studies on antiseptics and antibodies, tetanus, etc. Much of the material has already appeared in separate papers in British medical journals. The book will be useful to laboratory workers.

Medicolegal

Giving Treatments Regardless of Ailments

(State v. Fenter (Mo.), 204 S. W. R. 733)

The Springfield (Mo.) Court of Appeals, in affirming a judgment of conviction of the defendant, a chiropractor, of illegally practicing medicine and surgery, says that he contended that he was entitled to an instruction to the effect that, if he treated or attempted to treat Mrs. Mustain at her request and without any reference to her ailments, or whether she was sick or well, the jury should find him not guilty, and that he requested such an instruction, which was refused. If such a mental attitude on the part of the defendant could be tortured into a defense to the charge of treating the sick and infirm without complying with the law regulating the practice of medicine and surgery, then the law would be practically a nullity. Besides, there was no substantial evidence on which to base such an instruction. The defendant testified that in the particular case of Mrs. Mustain he did some work on her spine with his hands that might be called manipulations, and applied force with his hands to her spine, but did not represent to her that it was a corrective agency, or that it would take five or six or seven adjustments. The evidence further showed that the defendant treated Mrs. Mustain at his office several times, and visited her eight times, and made regular charges. In the defendant's office were an operating or manipulating table, an electrical machine, charts of the spinal column and nervous system, and the backbone of a human [illegible] at the entr[illegible] of the stairway [illegible] to the [illegible] sign indica[illegible] character of his business, and a like sign on his office door. Mrs. Mustain went to the defendant for treatment for physical infirmities, and he treated her; and if it were conceded that he did not tell her the purpose or object of the treatment he was giving, that could make no difference. Mrs. Mustain knew the purpose or object intended by the treatment, and that was to give her such relief as the treatment might give. The court thinks that the instruction was properly refused.

Valid Contract of Third Party to Pay Bills

(Meyers v. McKillop (Calif.), 173 Pac. R. 773)

The District Court of Appeal of California, Third District, in affirming a judgment rendered in favor of the plaintiff for services rendered by him as a physician and surgeon, and by his assignors, a Dr. Johnson and the Sacramento Valley Hospital, a corporation, says that the only question was whether the evidence warranted the court in finding that the transaction between the plaintiff and the defendant created an original or primary obligation on the part of the latter, it being the defendant's contention that he was, at most, a guarantor, and that the obligation was void because not in writing. The facts were similar, and the same question was presented in the matter of the two small assigned claims. This court thinks there can be no doubt that the theory of primary liability adopted by the trial court found sufficient support in the record. The services were performed for one Williams, and the plaintiff was called to attend him, October 5. Two days thereafter, according to the plaintiff's testimony, he had the following conversation with the defendant at the Sacramento Valley Hospital:

> I asked him whether he would pay Mr. Williams' bill. I told him I had an understanding he was going to pay the bill, and he said he would. I told him perhaps we had better make the sister feel more easy about the money. When we went down stairs, I repeated the conversation in front of Sister Marie, and the substance was that he was to pay Mr. Williams' bill.

He furthermore testified:

> I made three calls on the 7th; on the 8th three calls; on the 9th there were five calls made; and on the 10th he was operated on by myself, Dr. Johnson and Dr. Wilson. I called on him twice subsequent to the operation; on the 11th I called three times; on the 12th I called four times; and on the 13th three times the day he died.

These services, performed after his conversation with the defendant, were reasonably worth, so he said, the sum of $305, and this was allowed by the court.

It is a fair inference from the foregoing that these services were performed on the reliance that the defendant would pay, and it is also a fair inference that the latter directly promised to make such payment. This constituted an original contract, with a sufficient consideration for its support. It was true that the plaintiff was originally called by one Barnholdt, but there was no evidence that he was employed by the latter or by Williams, or that he looked to either for his compensation. At any rate, this court may eliminate the services performed on the 5th and 6th, as did the trial judge, and consider only what was done after the conversation with the defendant. This may be considered a separate and distinct contract, and this court sees no legal obstacle in the way of enforcing it. It was true that the defendant denied any agreement for the payment of the claim, but the court below obviously did not believe him, and this court cannot say that the want of faith was not justified.

There was a finding, following the allegation of the complaint, that

> Within two years last past plaintiff within the county of Butte, state of California, rendered medical and surgical services to one F. J. Williams at the special instance and request of the defendant, and defendant promised and agreed to pay the value thereof.

The allegation in the complaint was certain and definite enough to withstand the general demurrer which was interposed, and the exact time covered by the services for which the defendant was held liable was revealed by the evidence; the amount found due corresponded exactly with the testimony as to the value of these services; and this court sees no merit in the claim that it did not appear from the findings what period was covered by them.

Society Proceedings

THE INSTITUTE OF MEDICINE OF CHICAGO

Meeting held Feb. 21, 1919

The President, Dr. Hugh T. Patrick, in the Chair

SYMPOSIUM ON INFLUENZA

Epidemiology of Influenza

E. O. Jordan: The present epidemic has a much higher mortality than has been recorded in any of the other outbreaks of which I have been able to find record. The epidemic of 1890 was more severe than that of 1848, and the present epidemic was more severe than that of 1890. In the state of Massachusetts the deaths in 1890 amounted to 2,500; in the present epidemic, to 15,000—six times as many; and yet the population of Massachusetts had not quite doubled in twenty-eight years. The U. S. Census Bureau in its last report recorded 136,000 deaths from influenza and pneumonia in four years, while during this epidemic there have been from 600,000 to a million deaths from influenza and influenzal pneumonia in the United States since the middle of September. This number of deaths from influenza and influenzal pneumonia does not represent all the deaths due to this infection. I have recorded the number of deaths in the four large cities in the country, deducting the influenzal pneumonia component. These figures are for the month of October alone. In the city of New York there were 1,400 more deaths in 1918 after the influenzal pneumonia component had been deducted, and the same in Chicago, an increase of nearly 600 deaths. In Philadelphia and Baltimore, where the epidemic was more severe, the increase is more marked—an increase of more than 50 per cent. in Baltimore, deducting the influenzal pneumonia component; that is to say, there has been a large number of deaths reported from other causes that really ought to be attributed to influenza. Some of the deaths are reported under organic heart disease. For the month of October, 1917, in New York there were 464 deaths, to 1,228 in the same month of 1918. In Chicago there were 232 in 1917, against 512 in 1918. In Philadelphia the number was almost doubled.

In the number of deaths from pulmonary tuberculosis, there was an increase from 644 to 826 in 1918 in New York, and the same rate of increase occurred in Chicago and Philadelphia.

There were 362 deaths from congenital disease in New York in 1917, against 515 in 1918; 175 in Chicago in 1917, against 225 in 1918, and 107 in Philadelphia in 1917, which total was more than doubled in 1918. It is impossible to tell at this time what proportion of those deaths are due to influenzal infection of the mother, or what proportion to lack of care in the first six weeks of life, so that altogether the increase amounts to about 7 per cent. of the reported deaths from influenza and influenzal pneumonia in the largest three cities of the country.

Another matter on which a good deal of comment has been made has been the remarkable age incidence of influenza. In the week of maximum mortality in Chicago, the deaths between the ages of 20 and 30 were more than fifteen times as many as in the corresponding week of 1917. In the period from 5 to 10 there were 5.8 times as many deaths as in the corresponding week of 1917. This method of record is different from the one usually employed in that it shows the actual increase in deaths at all ages from influenza. There has been a marked increase not only from 20 to 30, but also at definite ages below 20. It has sometimes been suggested that the reason for the high mortality of the disease in the 20 to 30 group has been that this group did not show the effect of immunity from the preceding epidemic of 1890, while in those ages over 30 the patients might have had the disease in 1890 and so were protected against the present infection. That cannot be a true explanation. There are a number of reasons for that, and one of them comes out here very plainly. In the 30 to 40 age group, the members of which might have had the infection in 1890-1893, the mortality is considerably higher than in the 10 to 20 groups, where no such immunity could possibly exist. That comes out more strongly in the six weeks' maximum mortality, in which in the 30 to 40 age group the excessive deaths were 6.5, while in the 10 to 20 group the mortality was only 4.8, showing a much higher mortality in those who might be supposed to have had influenza in 1890.

In general, about one third of the whole population of the country seems to have been attacked. This tallies very closely with what has been observed in other epidemics. About 2 per cent. of those attacked with influenza died. This would give about 30,000,000 cases of influenza with 600,000 deaths.

One other point may be of interest in respect to the occurrence of this disease in two of our groups designated by A and B. This refers to two divisions of the Students' Army Training Camp of the University of Chicago last fall, living under the same conditions, housed in fraternity houses, remodeled apartment places, etc. In Section B, ninety-two cases of influenza occurred in about six days. During the corresponding period only twenty-six cases occurred in Section A. The difference between the two groups is briefly this: Section B was composed of men who came to Chicago from various small towns in Illinois about the middle of October. Three of them were ill on their arrival in Chicago. Other cases developed very shortly, so that in six days there were ninety-two cases. Section B was not brought to the attention of the university authorities for four or five days, and the men who were ill were in contact with the others during this period. The difference between the conditions in Section B and in Section A was that in Section A from the onset the men were under the closest supervision, and those who were slightly ill were at once removed; the results were that all through the epidemic these were only slightly affected. The two groups were exactly similar as regards housing and as regards care, except that the men who were ill were allowed to remain in contact with the others in Section B, while in Section A those who were ill were at once isolated.

Influenza at Camp Taylor

Dr. W. W. Hamburger: The epidemic lasted from Sept. 22 to Oct. 25, 1918. From the latter date on, sporadic cases came in. Up to December 17 we had 12,742 cases with 822 deaths, a mortality of 6.45 per cent. During the period of the epidemic there were 72,000 troops in camp; the gross mortality, therefore, was 1.14 per cent.

We had at one time a 9,000 bed hospital. We had from 500 to 1,000 new cases every day. We had about 250 cases of pneumonia developing a day. Our highest death rate was 80 in twenty-four hours. We had from 150 to 200 medical officers and from 300 to 500 nurses. We had a pneumonia ward of 2,000 beds. We had a ward of from 3,000 to 4,000 beds for new cases of influenza, and a ward of from 1,500 to 2,000 beds for convalescent patients. These three hospitals were under the direction of the chief military head of the hospital. We had to plan twenty-four hours ahead so as to arrange for new beds.

The height of the epidemic was reached nine days after its beginning. Then there was a drop, a pseudocrisis, a secondary rise, and then a permanent drop. The pneumonia curve is interesting. In the early cases the patients died on an average in three days. Toward the height of the epidemic the duration of the pneumonia was increased from three to four days, showing a prolongation of the pneumonia period, as the result, perhaps, of the patients making a better attempt to fight the disease. The chronological chart of necropsies shows the change in the general pathologic picture from week to week. There was a change in the involvement of the liver, as shown in the increase of hemorrhagic hepatitis. There was a change in the suprarenals, first showing hemorrhage, and the second stage showing congestion. The proportion of lobular pneumonia, that is, the hemorrhagic type, was very great in the first week. This was followed later by an empyemic picture with less hemorrhage. Changes were found in the terminal ileum and transverse colon, an ileitis. These were found in the first week particularly in cases with blood in the stools. In the skin we found quite regularly a condition like the one found in the ileum, a vesicular eruption. Cultures showed staphylococcus. Three conclusions were arrived at from our study of this disease:

1. Influenza is a disease that involves the entire body, involving the head and head sinuses, brain and meninges rather regularly. It involves the entire pulmonary tract, as shown by the hemorrhagic bronchitis and pneumonia. It involves the abdomen, as shown by the cloudy swelling of the liver, kidney and spleen, and by the clinical picture of hemorrhage, and the condition of ileum and colon. It involves the skin, as shown by the vesicular eruption. The pneumonia that develops is the most important thing. From our observations influenza is a generalized process, particularly striking, with an involvement rather constantly of all the sinuses of the head.

2. Influenza, as we saw it, was a progressive disease. The picture of the first week was quite different from that of the second and third weeks. In the first week the tendency to hemorrhage was striking, there being hemorrhagic sputum and hemorrhage from the lungs and the bowels. As immunity was established, this hemorrhagic tendency became less. Our conclusion from this was that the very early infection was very violent and the efforts of the tissues to withstand the disease was evidenced by the hyperemia. In the first week the patients died within twenty-four hours, showing a generalized hyperemia. In the second and third weeks this condition changed to a consolidation in the lung.

3. The early cases showed rather strictly the influenza bacillus. In the second and third weeks the Pfeiffer bacillus in the sputum was taken over by the pneumococcus. Recent laboratory tests in the new cases disclose an increased number of influenza organisms in the sputum and postmortem cultures. The necropsies in five cases made early in the epidemic showed Pfeiffer's bacillus with no other organisms, while ten cases in the fourth week showed pure pneumococcus with no influenza bacilli. From this we concluded that if the influenza bacillus was found, it might be an indication of the disease, but nothing else.

Bacteriology of Influenza

Dr. D. J. Davis: A real contribution will be made to bacteriology if the present epidemic enables us to establish the relation of Pfeiffer's bacillus to influenza. In the epidemic of 1918 I examined sixty two cases, in which the influenza bacillus was present in 8 per cent. In the epidemic of so-called grip in 1905, I examined seventeen cases, in which the bacillus was present in 17 per cent. In another epidemic of so-called grip—I do not call these cases real influenza—in twenty-three cases the influenza bacillus was present in 18 per cent. In twenty-six cases of ordinary pneumonia examined in the 1908 series, the bacillus was positive in 38 per cent. In lobar pneumonia the bacillus was positive in 33 per cent. In sixty-eight cases of pertussis it was present in 89 per cent.; in measles in 56 per cent.; in varicella, in 64 per cent. It is an interesting fact that in chickenpox these organisms were often present, and certain investigators have found them in 100 per cent. In eleven cases of acute articular rheumatism, the bacillus did not occur. In pneumococcic meningitis, the bacillus was present in 11 per cent.; in 300 cases of tonsillar crypts, it was present in 1 per cent.; in normal throats, it was present in 10 per cent. I take these results as comparative. I am not prepared to say that I found the influenza bacillus present in all cases, but I think they are comparable because the same method was used in all these examinations.

The reports of the present epidemic gave a very considerable percentage of Pfeiffer's bacillus in lung punctures and postmortem material, the percentage of some observers reaching 70 or 80. Pfeiffer himself has not been able to find the bacillus with any degree of constancy in this epidemic. It is interesting to note that the Germans and Swiss lay more stress on the diplostreptococcus than on Pfeiffer's bacillus, while England laid more stress on Pfeiffer's bacillus. A few studies on the presence of specific antibodies in the blood have appeared.

I think we are justified in saying that the influenza bacillus is not the cause of the present epidemic for these reasons: [illegible] bacillus is not the cause because it is found in any [illegible] is found in diseases like rheumatism, pertussis or measles. 2. Animal inoculation has never produced it. 3. The influenza bacillus is a diplococcus. It causes leukocytosis, and the primary blood picture in influenza is leukopenia. 4. Influenza is a disease prone to secondary invasion. Prophylactic influenza inoculations have failed to furnish any protection against the disease. 5. There are as good reasons for saying that the influenza bacillus is the cause of pertussis or measles as for saying that it is the cause of influenza. 6. There are as good reasons for saying that the diplostreptococcus is the cause of influenza as for saying that Pfeiffer's bacillus is the cause.

As to other associated organisms in this disease, the diplostreptococcus and other streptococci are found. They are not so numerous in the sputum in the early days of the disease as in a normal throat. Under ten days my figures were 31 per cent, positive, and after ten days, 65 per cent. The so-called diplostreptococcus is perhaps the most direct cause of influenza pneumonia, and in the epidemic of 1889-1890 these were found repeatedly and were considered a cause by Ribbet and others. Mathers in this country very early discovered this organism and considered it as a cause. Nuzum and others have also found it. The general agreement seems to be that all the above-mentioned organisms are secondary invaders, and I think we are justified in this belief.

Experiments with a filtrable virus are not conclusive. Many more are necessary. It is difficult to explain the negative results with such material as unfiltered blood. They are not in harmony with our ideals of the disease.

The Pathologic Anatomy of Influenzal Bronchopneumonia

Dr. E. R. LeCount: Published in The Journal, this issue page 650.

Clinical Aspects of Influenza

Dr. Solomon Strouse: From a clinical point of view it makes no difference by what name a disease is called. To most clinicians this is essentially a new disease, and in order to explain it we have to be in a state of mind free from bias. I hesitate to paint the picture of a disease which in December was so different from that in September and October. It is necessary to paint it from each phase. The disease was most severe in late September and October. It gradually waned during November, and in December another wave appeared that was quite different from the first wave. In January we can see patches of color from both of the preceding waves.

The incubation period is twenty-four hours. The onset occurs with acute fever without a definite chill; there is cough, and there are symptoms of pharyngitis. The greatest extent is from two to twelve days or longer, depending almost entirely on the extent of the primary pulmonary involvement. Complications are few—empyema, lung abscess and otitis media. The sequelae are multiple. The febrile prostration is the most constant after-effect.

The December wave showed a slight involvement of the nasal membrane. In October the throat showed merely an irritation of the anterior pillar. Recently, in January, an intense redness was found in the throat. It will take many thousands of carefully examined cases to ascertain the percentage of lung involvements. That pneumonia, generally lobular, but sometimes lobar, is the most serious accompaniment of the disease is recognized by all clinicians. I myself do not consider pneumonia a complication. It seems to be one form of the infection. There was no common course. Today we might find small patches of râles. This might disappear, to be replaced by another, or it might turn into a frank lobar pneumonia or lung abscess. An acute hemorrhagic pneumonia with only a few râles was not unusual.

The general appearance of the patient and the degree of mental disturbance gave the only points of value in determining the severity. In the beginning, the disease was much more violent. The patient would be ill only twelve or twenty-four hours. All these patients died.

Cardiac dilatation, which has always been described as occurring in regular pneumonia, appeared in this disease rarely except at the end of a toxemia. Cyanosis was marked. In some instances the lips looked as though they were painted with blue paint. Some of the patients looked as though they were suffering from acidosis, though that was not found. In some instances, acute hemorrhagic edema appeared like the ghost of peace when everything seemed to be going nicely. It looked as if the only cause of death could be in the brain. As Dr. LeCount mentioned, everything known and unknown in pathology was found.

The changes in the patient from day to day made it very confusing. We learned early in the epidemic that fever after the third or fourth day usually meant pulmonary involvement, and yet in some cases repeated examination failed to reveal any signs. Sometimes it was due to hyperthyroidism of pulmonary tuberculosis.

In Chicago, otitis media occurred as a complication, but nothing like in the proportion of 1890. Perhaps the only good thing about the disease was the repair in the lung. In many of the severe cases with lung changes in which the patient finally became well, the lungs showed almost complete repair fuctionally.

Complicated by other disease, influenza seemed to be no more severe than uncomplicated. Every one knows that the combination of pregnancy and influenza caused the highest death rate, perhaps 60 per cent. Later the general fall in the mortality included this group.

From October 1 to January 31, we treated 655 cases of influenzal pneumonia at the hospital. The average death rate in the 655 cases was 6.1 per cent. Our nurses' and physicians' mortality shows most strikingly in the statistics the comparative contagiousness of the disease. The physicians and nurses in the influenza ward who contracted the disease and the number who died were out of all proportion to the rest of the hospital personnel.

As to treatment, practically every form of drug was used. We spent days and nights trying to find out what to use, and at the present moment I do not hesitate to say that with the exception of salicylic acid, possibly an opium alkaloid or even a saline expectorant, and digitalis when necessary, the patient is better off if given no medicine. The patient should be put to bed early and kept there. This applies not only to the patient who has pneumonia, but also to the patient who is only mildly ill, who has just a slight discharge from his nose. He should be put to bed and kept there until one is sure what is going to happen, because this patient may develop a serious pneumonia.

The after-effects have been many. In some cases extreme physical fatigue was due to weaknened heart muscles, though endocarditis was not a common complication. Psychosis was extremely rare—I saw only two cases. Loss of hair and mild menstrual disturbances have been exceedingly common. Persistence of cough and pain in the chest for weeks after the disappearance of the disease have been so common without pulmonary findings that not much attention is paid to them. Hyperthyroidism is beginning to show up—perhaps only in patients who had the disease before.

Influenza from the Standpoint of Public Health

Dr. Heman Spalding: To combat influenza in a large city where there are big industries and a large number of persons employed is an entirely different problem from that presented in the small cities. To stop all great industries, street cars and factories would throw out of employment thousands of persons, who would suffer from want of the necessities of life. Such a course would cause more deaths from sickness and hunger than would be saved by shutting down these activities.

Persons ill of the disease should be isolated. Children in contact with sick families should be excluded from school for eight or ten days. When an epidemic comes on in the form of an avalanche, quarantining in the usual way is practically impossible. Under such conditions the best we can do is to isolate the infected person. A mask properly worn and changed several times a day no doubt helps to protect against influenza; but as it is worn by most people and would be worn, it is worse than useless. I believe that the vaccine used in Chicago helped to keep the people from becoming panicky.

Discussion on Influenza

Dr. Robert B. Preble: It might be of interest to the members to hear something or other of the experiences which the

Army abroad had with the influenza epidemic. This epidemic began in the spring of 1918, was moderately severe, and then disappeared. Along about the middle of September we began to have cases of pneumonia, and we found the hemolytic streptococcus both in the sputum and at necropsy. In the course of a very short period we began to find influenza bacilli, and these increased without our being able to detect any difference in the clinical manifestations of the disease or in the pathologic findings. Then the influenza bacillus began to disappear, and the whole thing was over. We had far fewer cases than you had here, and the cases were obviously milder in type. For example, in a camp of 25,000 men we had only 500 cases of pneumonia, with a mortality which ranged as high as 33 per cent. As the streptococcus influenza went down and the pneumococcus became more common, the mortality fell to 10 per cent.

Another curious observation we made was that influenza developing among surgical patients was unaccompanied by mortality. None developed pneumonia. This was curious because most of these patients had septic wounds, and we had a great many septic compound fractures; yet none of these patients developed pneumonia, and we had no mortality.

Dr. Julius H. Hess: I want to report a very interesting little group of cases that we had at Fort Benjamin Harrison. In a measles and streptococci pneumonia epidemic previously many of us had the idea there that there was some association between the high mortality and the typhoid vaccination. In the second week of the epidemic at Benjamin Harrison thirteen fresh recruits from North Dakota came into camp. They had not had triple typhoid vaccination. In that number the mortality was exactly the same as in all the other cases at camp that had had the typhoid vaccination.

In the symptomatology there was one point that stood out so prominently that I think it ought to be included as a prominent early symptom: the gangrenous odor on the breath of these patients. When one went into a ward that was not ventilated properly, the odor was just the same as one gets on coming into contact with an abscess of the lung. This odor was found in the first forty-eight hours, so it could not be associated with later complications.

We found that more than 70 per cent. of our throat smears and sputums showed a large number of Vincent's organism, a fusiform bacillus and spirilla. Whether this was a coincidence or not we do not know. In one instance we got a pure culture of fusiform bacilli.

Dr. Peter Bassoe: If we were to read up the history of epidemics, we would find that in every epidemic of influenza there have been a large number of nervous complications. As far back as 1740 it was noted in an epidemic that there were many cases of nervous disease characterized by somnolence. In 1889 and 1890 there was an epidemic going over Europe without a marked mortality, but with a complication that was thought to be an encephalitis affecting the brain stem. This was known at that time as "nona," a name that has since been forgotten. In 1918 in England, in Austria and in France, there was described a condition called lethargic encephalitis, characterized by fever, headache, drowsiness, and more or less paralysis of the cranial nerves, particularly the ocular nerves. After a time it was thought to be a form of poliomyelitis, but it had none of the ordinary poliomyelitic symptoms. Finally, it was pointed out by a French surgeon that it was probably an influenza infection. The mortality was given as, I think, 25 per cent. in England and 35 per cent. in France. Now in the last few weeks there have been a number of such cases in Chicago. I myself saw six. Dr. Tieken saw six or seven. These cases have all been very much alike, characterized by very marked drowsiness, no cell increase in the spinal fluid, no headaches, and more or less cranial paralysis. I have seen some of the patients brought in with a facial paralysis and some with an ocular paralysis. I have a couple of cases under observation now. They show a very marked rigidity which is very similar to the rigidity we see in paralysis agitans. I think it is wise for us to be on the lookout when patients who have had influenza become very drowsy and then develop cranial nerve paralysis.

E. O. Jordan: I should like to say just a word about some observations on the bacteriology of these findings, as it has a bearing on what has been said in regard to the different types in different sections. In our group, Section B, where there were ninety-two cases, we very rarely found Pfeiffer's bacillus in any of the smears throughout this epidemic. They could be found in a few cases by searching very carefully. At the same time, in October, in the cases obtained from the hospital, Pfeiffer's bacillus was found in considerable numbers. In this case it would seem to be a group affair. As to death rates, Philadelphia and Baltimore seemed to have much higher death rate than other large cities. New York and Boston had lower rates. Some cities in this neighborhood, Milwaukee, St. Paul and Minneapolis, had lower death rates than Chicago.

*Intestinal Contents of Newly Born Infants. A. Hymanson and M. Kahn, New York.—p. 112.
Sleep in Children and Its Disturbances. A. Strauch, Chicago.—p. 118.

Fetal Bronchiectasis.—Koeckert reviews the literature on this subject and reports one case, in many respects similar to the other cases of fetal bronchiectasis of the Sacklunge type, in which an analysis of the cyst fluid was made. It closely approximated liquor amnii.

Intestinal Contents of New-Born.—The meconium of five infants, voided during the first twenty-four hours of extra-uterine life, was analyzed by Hymanson and Kahn. The iron and calcium contents were similar to those obtained in hunger feces. The phosphorus of meconium was less. The sulphur was much increased. Traces of ammonia were found in the meconium. No uric acid was found. This fails to corroborate Weintraud's analyses. Amylase was present in extremely faint traces. Neither trypsin nor erepsin were found. No lactase nor lipase was found.

*Modification of Bradford Fracture Frame. A. S. Hyman, Boston.—p. 183.

Modification of Bradford Fracture Frame.—Hyman's modification of the Bradford frame consists of an upright frame attached to the bottom of the Bradford. To this upright connected a sliding bar which supports an adjustable pulley carriage. The sliding bar is fastened to the top and bottom of the upright with an adjustable brace. With the extension apparatus thus applied directly to the Bradford frame, it becomes possible to move the patient in bed from place to place without the slightest possible change in the position of the fragments of the fractured bone. It does away with the "hood" that is used to protect the feet of the patient from the weight of the bed clothes—the upright itself acts as a hood on which the sheets can be fastened. The apparatus can be used in the treatment of septic conditions of the leg or foot which require elevation and traction. Counter extension is easily obtained by placing suitable blocks under the bottom of the frame. Hyman believes that this apparatus will supplant Buck's extension apparatus.

Symptomatology of Epidemic Influenza.—Most of the patients on whom Bloomfield and Harrop report were seen from the very onset of symptoms and went through their illness without complications, thus affording an unusual opportunity to study the clinical features of the entire course of the disease. The mortality among these 268 cases was 4.8 per cent.; forty-one developed pneumonia, with a death rate of 32 per cent. The disease was ushered in by two groups of symptoms; in the first place the constitutional reactions of an acute febrile disease—headache, general aching, chills, fever, malaise, prostration, anorexia, nausea or vomiting; and in the second place, symptoms referable to an intense congestion of the mucous membranes of the nose, pharynx, larynx, trachea, the upper respiratory tract in general, and of the conjunctivae. Three distinct types of invasion were noted—abrupt invasion, gradual invasion and invasion with intermittent symptoms. Of particular interest were certain symptoms that were present within the two weeks preceding the onset, but which apparently were independent of the actual disease. In general, these "preonset" symptoms were in the nature of mild upper respiratory tract disturbances of from one to two weeks' duration, usually improving or well at the time of definite onset of the influenza.

The general appearance of the patients was most striking. In well marked cases, there was an intense, dusky, reddish-plum-colored erythema of the face, lips and upper chest, which usually faded off abruptly at the level of the breast, but in some cases extended over the entire chest and back, and occasionally involved the arms and legs. Early in the course of the epidemic the authors noticed an unusual bright red appearance of the throat in most of the patients, and more careful study of subsequent cases showed this to have striking and constant features. The changes in the mouth usually became full-blown during the first twenty-four hours of the disease. The most striking feature is a bright vermilion or scarlet injection of the pharynx, tonsils, pillars and soft palate. In many cases, this erythema extends over the entire mouth, and can be demonstrated by pressure on the mucosa of the cheek with a spatula. In the most marked cases, the entire mouth cavity has a flaming appearance. The tongue is usually coated, but if clean is bright red like the buccal mucosa. In from one half to two thirds of the cases at onset, one to three or four, or even more, dark crimson spots were seen on the mucosa of the inside of the cheek. The individual spots fade rapidly, disappearing without trace in from one to two days. They may reappear in repeated crops in the same individual, and are seen in convalescence in most of the cases. Another striking feature in the appearance of the mouth was a swelling of the minute nodules normally present on the soft palate. Once fully established, the disease picture was remarkably constant.

In the severer cases, a febrile albuminuria was present, usually clearing up promptly after free intake of water. The blood pressure was either normal or low. Low readings were especially frequent in the very asthenic cases. Leukopenia was the rule during the active stage of the disease. Apart from pneumonias, complications were few. The authors are convinced that epidemic influenza in 1918 is clinically identical with the disease as seen in previous pandemics, and that it is primarily a local disease of the respiratory tract. It presents a definite and characteristic clinical picture quite apart from pulmonary complications. The main features of the uncomplicated disease are a constant set of symptoms, characteristic erythema and appearance of the mouth, fever of determinate duration, and leukopenia. Proof is lacking that Pfeiffer's bacillus is the primary cause of uncomplicated influenza.

Behavior of Blood Toward Oxygen in Influenzal Infections.—The determinations included in Harrop's report were made in nine cases of postinfluenzal bronchopneumonia, three of them fatal, and in four uncomplicated cases of influenza, in the early hyperacute stage, when the characteristic dusky erythema or "cyanosis," was most striking. The oxygen content of the venous blood was determined by Lundsgaard's method. Both oxygen content and oxygen unsaturation showed normal values in uncomplicated influenza cases. In none of the cases of bronchopneumonia which recovered, and not until the terminal collapse in the fatal cases, has the venous oxygen content or the amount of oxygen unsaturation been abnormal. The values seems independent of temperature, pulse, respiration and extent of lung involvement. In two fatal cases with septicemia, after terminal collapse, there was a progressive fall in both the oxygen-combining power and the oxygen content of the venous blood, in general parallel. There was no increase at any stage of the disease in the values for the oxygen unsaturation of the blood.

Bacteriologic Findings in Epidemic Influenza.—The cultures reported on by Howard were taken from the cases reported in the paper by Bloomfield and Harrop. Cultures were made from the nasopharynx, the sputum and the blood. Among the organisms found were *B. influenzae*, green streptococci, pneumococci and staphylococci. The authors feel that none of the organisms isolated may be regarded as the cause of epidemic influenza. They are convinced that the *B. influenzae* of Pfeiffer is merely a secondary invader, though in some localities it may be a frequent cause of terminal bronchopneumonia. The other organisms isolated may also be regarded either as normal inhabitants of the mouth or as secondary invaders. The primary cause of epidemic influenza, therefore, is still unknown.

Ectopic Pregnancy.—Three hundred and three cases of ectopic pregnancy were analyzed by Wynne. This is an incidence of 1.3 per cent. of 22,688 gynecologic patients. Of 275 patients whose history as to previous pregnancy is recorded, fifty-seven had never before been pregnant. Forty-five patients had had operations prior to admission for ectopic pregnancy. The most common causes for which these patients sought medical attention were pain, complained of by 254; bleeding, complained of by ninety-three, and tumor, complained of by twenty-two patients. A history of abdominal pain was procured from 300 patients; the other three patients stated positively that there had been no abdominal pain nor discomfort, and they came to the clinic on account of irregular bleeding. In each of these three patients an unruptured tubal pregnancy was found at operation, but no evidence of any clot or free blood in the peritoneal cavity. Recurring attacks of pain occurred in 102 cases; seventeen patients complained especially of soreness and tenderness, rather than of definite pains. The character of the pain was described as violent, agonizing or severe in ninety cases, cramping in forty-one, colicky in four, bearing down in fourteen, labor-like in nine, shooting, cutting or sticking in 6, and as dull or aching in twenty-nine. One hundred and three patients stated definitely that they had missed one or more periods; and thirty-one said that their last period had been overdue for from one to five weeks, while fifty-two had noticed that the last period was abnormal in some other respect. The author emphasizes the fact that diagnosis of the cases is not so easy as many writers consider it.

The treatment of these cases (272) was operative, either by the abdominal or vaginal routes. In several cases posterior vaginal celiotomy was performed for diagnosis. Pelvic puncture was employed for pelvic hematocele in a number of cases, although in 60 per cent. of the cases a laparotomy was performed immediately afterward. In only fifty-five cases had rupture not occurred; 266 cases were tubal pregnancies; two were interstitial and 2 two were ovarian; 131 were on the left side, the remainder on the right. There were thirteen deaths in the series of 303 cases. Of 120 patients, 100 have been well since operation. Of 127 patients, there was no possibility of future pregnancy in thirty-three. Of the remaining ninety-six, in whom there was a possibility of future pregnancy, thirty-six have since become pregnant one or more times, and six patients had a second extra-uterine pregnancy.

Chemical Changes in Tuberculous Tissues.—For the sake of comparative results, Caldwell made analyses of normal as well as tuberculous tissues. Lymph glands and liver tubercles were used exclusively for the tuberculous specimens, and normal glands and livers furnished the materials for comparison. Many of the findings of other workers in this field, notably Wells, are confirmed. For details, the original article should be consulted.

Gram-Negative Bacilli in Renal Infections.—A classification of eighty-six different strains of colon bacillus-like organisms by means of cultural, fermentative and serologic methods is made by Herrold and Culver. These organisms were all secured by ureteral catheter from the kidneys and isolated by cultivation on blood-agar plates.

Complements in Wassermann Reaction.—Ruediger found that the complements of fresh guinea-pig serum varied greatly in fixability. Human complement gave much weaker positive results than did guinea-pig complement. Guinea-pig complement left on the clot and kept in the refrigerator remained fairly constant for three days, while complements which had been removed from the clots deteriorated more rapidly. Ramy's method of preserving complement by sodium acetate was a total failure in Ruediger's hands. Glycerol seemed to prevent deterioration of complement for a few days.

Pleomorphic Streptococci.—Pleomorphic streptococci which, according to Holman, would be classed as *S. salivarius* were found by Sherwood and Downs in the nasopharynx of approximately 25 per cent. of apparently normal persons. These organisms, as a rule, showed some pathogenicity for young rabbits, which develop agglutinins for the strains of organisms injected. Injected intracerebrally, the cocci remained localized in the nervous system throughout which they became disseminated. When injected intravenously they were found in the nervous system within three or four hours. After seventy-two hours they were present usually only in the nervous system. The common symptoms were rise in temperature and loss of muscle tone, with occasional flaccid paralysis and permanent impairment of the legs. The changes in the nervous system were hyperemia, frequently hemorrhage, increase in round and neuroglia cells and perivascular infiltration of round cells. The serum of normal persons frequently contains agglutinins for these organisms, occasionally in dilutions of 1:100.

Variation in Diphtheria Group.—Twenty-five cultures of members of the diphtheria group isolated from various sources were studied by Meader, and he found that variations in morphology, in fermentative reactions and in virulence occur in subcultures derived from one parent strain. The virulence of a strain is not closely correlated with its morphology, nor is it correlated with its fermentative reactions.

Effect of Magnesium Salts on Certain Bacteria.—The fact that Epsom salt has a salutary effect on the skin led Northrup to investigate the influence of magnesium sulphate on the organism commonly found in ordinary pimples, *Staphylococcus aureus*. It was negative. Streptococcus skin infections may, however, be inhibited if any concentration of magnesium sulphate is used externally. Magnesium chlorid had the most marked inhibitory action on the growth of all organisms used in the experiment.

Opsonins in Experimental Poliomyelitis.—A well marked increase in opsonin for the pleomorphic streptococcus in the serum of monkeys during attacks of poliomyelitis following the inoculation of virus was noted by Davis. Since this increase in opsonin occurs toward strains derived from human cases as well as from experimental poliomyelitis following the injection of virus, Davis says that the pleomorphic streptococcus in this disease cannot be regarded as an accidental invader of the nervous system.

Bacteria in Sputum in Measles.—Seventeen specimens of measles sputum were examined by Tunnicliff on the first or second day after the appearance of the eruption. Direct smears of the washed sputum showed the presence of a variable number of small (0.5 microns) round or very slightly elongated gram-positive diplococci, often in large numbers and frequently the only organisms present. The diplococcus was isolated from all of the sputum examined. *B. influenzae* and *S. hemolyticus* were each isolated twice.

Journal of Pharmacology and Experimental Therapeutics, Baltimore

December, 1918, **12**, No. 5.

*Pharmacology of Ureter; Action of Some Optic Isomers. D. Macht, Baltimore.—p. 254.
*Dichlorethylsulphid (Mustard Gas); 1. Systemic Effects an Mechanism [illegible] E. K. Marshall, Jr., V. Lynch and F. W. Smith, W[illegible] p. 265.

*Id. 2. Variations in Susceptibility of Skin to Dichlorethylsulphid. E. K. Marshall, Jr., V. Lynch and H. W. Smith; Washington.—p. 291.

Pharmacology of Ureter.—The action of optic isomers on the isolated ureter were studied by Macht. He found that in case of the different optic varieties of hyoscyamin, scopolamin, epinephrin and camphor, the pharmacologic action was different, and that the levogyrous variety in each case was the more stimulating than the dextrogyrous one.

Systemic Effects of Dichlorethylsulphid.—Dogs and fish were used by Lynch and his associates in this study. It was found that dichlorethylsulphid is absorbed through the lungs and produces definite, characteristic, systemic effects. The symptoms of injection of the substance are salivation, vomiting and diarrhea, tonic and clonic convulsions, slow and irregular heart, followed by a rapid pulse, and stimulation of the respiration. A dose of 6 mg. or less per kilogram, injected intravenously in aqueous solution, proves fatal for dogs. Dichlorethylsulphid appears to be excreted in the urine, in part, at least, as dihydroxyethylsulphid, which has been shown to be a comparatively nontoxic body. The lesions in the intestine suggest that excretion of the substance may also take place here. The authors advance as a theory of action that the dichlorethylsulphid penetrates the cells, and in the aqueous phase of the cell, hydrolyzes to hydrochloric acid which is responsible for the damage. Sodium bicarbonate in large doses somewhat alleviates the symptoms, but does not prevent death. Fish are much less susceptible to this substance when kept at a low temperature after exposure rather than at room temperature. The hydrolysis of the substance is much slower at a low temperature. Monochlorethylsulphid, and dichlorpropylsulphid are lipoid soluble and easily hydrolyzed. They both act similarly to mustard gas. The authors believe that dimethylsulphate acts by intracellar liberation of sulphuric acid.

Action on Skin of Dichlorethylsulphid.—Two methods were used by the authors for determining the cutaneous sensitivity of individuals to dichlorethylsulphid. The first consisted in exposing the skin to the vapors of the substance under constant conditions and determining the minimum time of exposure which is necessary to produce a visible reaction within twenty-four hours. The second method consisted in applying to the skin standard solutions of mustard gas in paraffin oil. The first method gave the most accurate results, although the second is very much simpler and more rapid in its application. Tremendous differences in sensitivity were found on the part of different individuals. A large group of white men tested showed about 2 to 3 per cent. of hypersensitive men and 20 to 40 per cent. of resistant men. Negroes, as a race, are much more resistant than white men. Sweating and moisture increase the sensitivity of the skin. Men may become more sensitive from continued exposure to the gas, and especially when severely burned. An atypical reaction is described in a man who became more sensitive from continued working with the substance; this appears to be of anaphylactic nature. The skins of ordinary laboratory animals were also tested. The monkey and guinea-pig were the most resistant, while the horse was the most sensitive. No animal exhibited a reaction at all similar to that in man. No animal has yet been found which will give a blister from the application of mustard gas.

The only factor in the general characteristics of the skin which would appear to have a distinct bearing on the question of sensitivity is the apparent thickness of the skin. Fifteen minutes after pure dichlorethylsulphid is applied to the skin it can be removed almost entirely by long continued rubbing with kerosene. This indicates that the substance is not immediately absorbed into the deeper layers of the skin. A resistant individual whose normal minimum burning time is four to five minutes and who does not react to the 1 per cent. oil solution, can be made to give a reaction to a fifteen to thirty second exposure of a 0.01 per cent. oil solution by covering the area of application with a glass cup immediately after, and leaving it covered for six to eight hours. It was found that when two vapor tests were made under identical conditions on the arm of a sensitive individual (five minutes exposure), and immediately after the exposure the arms of two individuals were impressed on each of the exposed areas for five minutes the burns were modified in intensity. If the recipients are respectively more and less resistant than the donor, that burn on the donor's arm given to the more resistant man will be the mildest. If a sensitive individual impresses his arm alternately against burns of the same concentration and exposure on a resistant and sensitive man, the recipient receives a more severe burn from the sensitive than from the resistant man.

This would indicate that the skin of a resistant individual displays a greater affinity or capacity for dichlorethylsulphid than that of a sensitive man. A tentative explanation of this phenomenon is offered. A three phase system is involved—the air over the skin surface constitutes the outer phase; some fatty or keratinous elements of the skin, the central phase; and a cellular portion of the skin the inner phase. The central phase is rich in lipoids and poor in water, while the inner phase is rich in water and poor in lipoids. After exposure to the vapors of dichlorethylsulphid the central phase is the absorbing agent and tends to establish equilibrium with the other two phases. On account of the lipoid nature of the central phase no damage is produced here because the compound is not hydrolyzed. On its passage from the central to the inner phase hydrolysis takes place within the cell and damage results when a sufficient concentration of hydrochlorid acid is attained. The outer phase is constantly being freed from vapor by diffusion and convection currents, so more and more can evaporate from the central phase. The susceptibility of an individual depends on the relative power of the central phase to hold the poison in an inactive form (not hydrolyzed) and prevent its entry into the inner phase at a sufficient velocity to result in the formation of a toxic concentration.

Reshaping Tool Handles for Use by Deformed Hands.—Using the composition prepared by Major Allen, and carrying out his idea in another direction, Shufeldt makes a rough model of a hand with ordinary gelatin and dental modeling compound, and when it is in plastic condition it may be made to hold any tool or instrument that the cripple (*mutilé*) desires to use at the time. This mold or composition hand may be detached and another screwed on in a moment, to meet what the man desires to perform. Then, too, it is an easy matter, and one that requires but a few minutes, to plunge this "hand" into hot water, remove the fork, insert a lead pencil or a pen, or anything else, for the matter of that, which the cripple desires to use next, dip the composition in ice water, and in a very brief space of time the member is ready for use as desired. An ingenious person may work in all sorts of useful designs—as a single finger that may be used on a typewriter—and for a great many other purposes. In other words, an artificial arm, with a detachable hand may, by this plastic hand attached, be made to be ten times more serviceable than the artificial hands as they are now usually manufactured.

Control of Hemorrhage from Large Sinuses of Brain.—Eagleton describes a special apparatus, combining an obturator and ligating principle, which he uses in these cases. He reports a successful operation for cerebellar abscess by obliteration of the lateral sinus and exploration and drainage through its inner wall and anterior surface of cerebellum.

False Teeth as Cause of Cancer.—The basis of Field's report is an analysis of a series of 87 clinical cases coming under his observation in which the initial ulceration or nodule was in close proximity to an artificial denture of which the patient offered complaint. Nineteen showed original development of the tumor adjacent to bridge work and 68 near plate work of various types. The malignancy presented in 59 cases in the superior maxilla as against 28 affecting the inferior maxillary region. The tumors were classified as follows: carcinoma, 65; sarcoma, 9; osteoma, 3; fibroma, 4; chondroma, 4, and melanosarcoma, 2.

Influenza and Pneumonia.—One hundred and thirty-one cases were carefully analyzed by Cowie and Bevan. It was noted that the respiratory rate is no guide to the *seriousness* of influenza pneumonia. The myocardium seems to be unaffected throughout the course of the influenza and the pneumonia. This observation was borne out by the necropsies made. A low leukocyte count is characteristic of influenza and influenza pneumonia. A leukopenia frequently occurs, but it is not the rule. Albumin and casts were not found in the straight influenza cases. They were present in 70 per cent. of the pneumonia cases. The authors regard their presence as indicative of pneumonia and of grave significance. Cyanosis was a nearly and almost constant sign of the pneumonias. In every case observed, pneumonia was demonstrated. In 67 per cent. of the influenza pneumonias the process started in the left base posteriorly. Bloody sputum was not always a grave symptom of pneumonia. Cases with pulmonary hemorrhages ended fatally. The authors believe that all deaths from influenza are due to bronchopneumonia.

Prophylaxis and Treatment of Influenza. L. T. de M. Sajous, Philadelphia (continued).—p. 288.

Etiology of Chorea.—The case cited by Graves and Paige is unusual because of its rather acute onset, apparently simultaneously with "rheumatism," its associated endocarditis and its postmortem pathology. The patient was ill only about three weeks. The final gross and microscopic diagnoses were: lobular pneumonia, vegetative endocarditis, acute toxic splenitis, toxic enteritis and appendicitis, toxic hepatitis and midzonal necrosis; toxic nephritis (early tubular), polypoid adenomata of cecum. The bacteriology showed pneumococcus from the lungs and heart's blood (septicemia five hours postmortem) and *Staphylococcus aureus* with pneumococcus from the right middle ear. This case offers several interesting features. Apparently a typical acute chorea made its appearance synchronously with acute infection. The spinal fluid was negative. Histologically the brain was negative. The authors suggest that the blood and spinal fluid be examined repeatedly, bacteriologically and serologically, in every case of chorea. It is possible that acute or Sydenham's chorea is due to the action of bacterial toxins, perhaps a selective action on central nerve cells, in persons whose inherited nervous instability makes them more readily subject to such toxic action.

Bacteriologic Examination of Sputum in Influenza.—The sputum of 53 influenza patients was examined bacteriologically by Williams. He found the following: pneumococci (probable) in 33 cases; streptococci (probable) in 17 cases; staphylococci and tetrads, in 24 cases; gram-negative cocci in 42 cases; Pfeiffer bacilli in 16 cases; other bacilli in 30 cases; hemolysis present in 23 cases. The sputum always contained two organisms in considerable numbers, and frequently three or more. The sputum did not contain Pfeiffer's bacillus in overwhelming numbers.

Congenital Anomalies of Kidney and Ureter.—The twenty-three clinical cases of anomalies of the kidney and ureter cited by Bugbee and Losee represent two single kidneys, both the seat of infection, one presenting a calculus obstruction of the single ureter; three fused kidneys; one horseshoe kidney, the seat of tuberculosis, and two fused kidneys apparently free from infection but causing pressure in their anomalous position. All six cases showing duplication of the renal pelvis had a pyelonephritis. The six cases presenting one or both kidneys in an anomalous position showed renal infection, one being tuberculosis, and another having a renal calculus. The six cases showing anomalies of one or both ureters all were the seat of real infection. It must be noted that but two of the cases presented renal infection which indicates that a single kidney called on to do double work, a malformed or malplaced kidney having poor drainage, poor blood supply and subject to pressure is prone to infection. Anomalies of the ureter also interfere with kidney drainage, thus predisposing to infection.

The necessity for assisting such kidneys to perform their function is apparent. The indications are to throw less work on the kidneys. With four exceptions the infections were all of the colon type. The necessity of attention to the intestinal tract is apparent. Lavage of the kidney pelvis has been beneficial, and permanent drainage with the ureteral catheter, often for several days, has proved efficacious. The surgical indications are to improve the drainage and relieve pressure, if necessary, by placing the kidneys in more nearly their normal position; to remove any obstruction to renal drainage (as a calculus) to remove a diseased kidney when destroyed beyond repair, if the opposite kidney is able to carry on the necessary function, or in rare cases to remove the kidney which cannot be replaced and is causing pressure symptoms due to its malposition. Whenever an abdominal mass is found, a renal anomaly must be excluded. If it is not possible to make a positive diagnosis of the extent of the lesion before operation, the operation should include an exploration of both kidneys.

Tubal and Ovarian Hemorrhage.—Abstracted in The Journal, June 22, 1918, p. 1975.

Operative Treatment of Chorio-Epithelioma.—The fact that he obtained eight recoveries in nine cases is attributed by Vineberg to the circumstance that the diagnosis was made at an early stage of the disease. The only fatality in the series occurred in the case of a patient who was subjected to two curettages, the pathological report of the first being misleading, although a tentative diagnosis, on the clinical evidence, had already been made by Vineberg. The author agrees with Pollosson and Violet, that the better results obtained in cases following hydatid mole are probably due to the circumstance that the cases are watched more closely, and the diagnosis, in consequence, is made at an earlier stage.

The treatment of chorio-epithelioma, once the diagnosis has been made, resolves itself into an immediate panhysterectomy, for there is no way of determining whether the individual case be a highly malignant one, or one that might undergo spontaneous cure. The latter contingency is so unusual that for all practical purposes it must be left out of consideration. When the growth is discovered while emptying the uterus of a hydatid molar pregnancy, the natural thing to do would be to complete the operation through the vaginal route. The same would apply when, in a doubtful case, an exploration of the inner and outer walls of the uterus would be made through a vaginal incision. In most all other instances, the abdominal route probably is to be preferred, for it embraces less traumatism and consequently less danger of causing metastases.

Vaginal Hysterectomy for Cure of Prolapse of Uterus.—Vaginal hysterectomy for the cure of prolapse of the uterus where the removal of the uterus is necessitated and fascial lapping is advocated by Bissell in all forms of vaginal prolapse. He describes his technic in detail.

Hysterectomy and Ovarian Function.—An abstract of this article was published in The Journal, June 15, 1918, p. 1885.

Pathology of Goiter.—Enlarged thyroids are classified by Simpson in five groups, namely: simple goiter, multiple adenomata, colloid goiter, exophthalmic goiter, malignant neoplasms. These are all characterized by the common factor of enlargement of the thyroid but otherwise differ markedly from one another. They may be differentiated clinically in nearly all cases by careful examination.

Etiology of Toxemia of Pregnancy.—The deduction made by Talbot is that the fundamental cause of toxemia of pregnancy with or without convulsions is not in the products of conception. In general the severity of the symptoms of toxemia is proportional to the amount of sepsis present. One of Talbot's cases was a marked exception to this statement. Talbot is convinced that to overcome the chronic sepsis which occurs in connection with the teeth, would surely eliminate the most potent cause of chronic nephritis.

Chronic Duodenal Obstruction.—Kellogg cites a case of duodenojejunostomy for duodenal ulcer which he believes is the first on record.

Three-Flap Operation for Extreme Pendulous Abdomen.—In this three-flap operation, which MacLean believes is the method of choice when the operative treatment is undertaken in the case of extreme pendulous abdomen, two long incisions, forming an ellipse, are made from one side of the abdomen to the other, the upper passing above the umbilicus, the lower passing about 2 inches above the fold where the abdomen hangs over the pubes. The skin and fat are dissected away from the external oblique aponeurosis until the ring of umbilicus is met. The abdomen is then opened at the umbilicus, and the mass dissected away from the umbilical ring. The part of the abdominal wall which has given way can be lifted up in the form of a cone with the umbilicus forming the apex. If the fingers be inserted within this cone the internal ring of the protusion can be felt at its base. The upper limits of the ring, while several inches from the umbilicus in the pendulous abdomen cases, is a point very close to the normal anatomic position of the umbilicus, and corresponds to the lowest linea transversea of the recti muscles. Two lateral incisions are now made from the umbilical ring to the inner margins of the recti muscles. A third incision is made from the umbilical ring downward to the firm lower margin of the internal ring where the recti muscles decussate. Three flaps are thus formed, two lower and one upper. The two lower flaps are overlapped from side to side, thus reducing by one half the space between the recti muscles. The free margin of each flap is stitched with strong chromic catgut to the firm margin of the sheath of the opposite rectus muscle. The upper flap is drawn upward, and the upper margin of this lower and now double flap is stitched to the upper margin of the so-called internal ring. The upper flap is next drawn and spread over the lower double flap and its margin stitched to the aponeurosis of the external oblique. The skin is closed, and three small tube drains are inserted, one at each angle and one in the center of the wound. In the place of the relaxed wall is now a threefold aponeurosis covering the opening and secured at every point to normal anatomic structures that have not yielded to the intra-abdominal pressure.

Evacuant Enema in Surgery.—The enema is regarded by Moore a more physiologic procedure for the preoperative preparation than the habit of giving a purge. He has operated on several patients without any other preparation, as far as the digestive tract is concerned. His routine procedure has been to have the patient eat as usual, giving a regular supper on the day previous to the operation. Following the supper, before bed time, an ordinary soap-suds enema of 1 quart is given. This empties the lower bowel. The patient is given plenty of water to drink during the night. Water should be offered the patient at intervals in the morning, whether asked for or not. At 6 or 7 o'clock in the morning another enema is given, usually with good, easy results. The patient has now one, two or three hours of rest before the operation is to be done, drinking water to within one hour of operation. Moore has noted that nausea is less frequent following anesthesia and operation where the enema has been used, as a result of the fluids being left in the tissues to be handled in the normal way.

Some Principles of Neurology. H. Head.—p. 344.

Unsuspected Involvement of Central Nervous System in Syphilis.—Fildes and his associates examined 624 syphilitic men, of whom the great majority were in the early stages of the disease and showed no obvious signs of nervous disease. Of these, 18 per cent. showed undoubted signs of an abnormal condition of the central nervous system. Of all men who had been affected for more than six months and showed no symptoms, no less than 35 per cent. had abnormal central nervous systems. The onset of the abnormality may occur very early. In two cases it was demonstrable before the Wassermann reaction had become positive in the serum after infection. The nature of this abnormality in the central nervous system does not admit of doubt. It is a syphilitic meningitis. The authors base this opinion not only on the presence of lymphocytes in the cerebrospinal fluid but also on the frequent appearance of polymorphonuclear leukocytes in the more pronounced cases. Furthermore, in a large proportion of the abnormal cases, the fluid showed a positive Wassermann reaction, while in one case *S. pallida* was found by the method of dark-ground illumination. There is no evidence that previous arsenical treatment increases either the number or severity of the affected cases.

An outstanding feature of these cases is the almost total lack of symptoms. Very few of the men complained of disability even when the meningitis was acute enough to produce a visible opalescence in the cerebrospinal fluid. Very few of these men showed any clinical signs of nervous disease detectible by examination. On the other hand, a considerable proportion of the abnormal cases had lesions of the eye grounds, which were of slight extent, but which, nevertheless, indicated a commencing retinitis. A certain number of patients showed affections of the internal ears, but there was no evidence that these were commoner than among nonsyphilitics or syphilitics with apparently intact nervous systems. Antisyphilitic treatment has a marked ameliorating action on these conditions. Some are rapidly reduced to normal, while the great majority were shown to be improved within the period of observation. On the other hand, a few cases showed a remarkable resistance to treatment; the meningitis actually progressed in spite of repeatedly renewed treatment. Although the demonstration of a negative Wassermann reaction in the serum denotes that an affection of the central nervous system is improbable, the authors do not believe that it is excluded, and in view of the importance of early treatment (and the value of the operation in prognosis) it is probable that lumbar punctures should never be omitted as a routine in the examination of all cases of syphilis.

Existence of Two Distinct Physiologic Systems for Transmission of Motor Impulses in Peripheral Nerves.—The two systems described by Hunt are a paleokinetic system subserving the function of automatic and associated movements, and a neokinetic system for isolated synergic movements of cortical origin. He says that there are spinal, striospinal and corticospinal types of motility, all associated and working together harmoniously and representing different stages in the development of the nervous system. According to the hypothesis formulated in the present study, these subdivisions are not confined to the central nervous system but are continued as such in peripheral nerves. The peripheral motor neurones, therefore, include two separate and distinct physiologic systems related, respectively, to the striospinal and the corticospinal systems. The older of these, the paleokinetic system, is engaged in the transmission of the motor impulses of automatic and associated movements, while the more recent neokinetic system conveys the motor impulses of cortical origin. In other words, with the specialization of the central pathways there has been a corresponding specialization and differentiation in peripheral nerves, with the development of separate systems of fibers for striatal and cortical functions. Hunt, therefore, recognizes a continuous corticospinoneural system subserving a neokinetic function and a striospinoneural system subserving the function of paleokinetic motility. It is his belief that these two motor systems are associated with the development of corresponding reflex activities, so that striospinal and corticospinal types of reflexes may be recognized. It would also appear that certain differences in the two classical types of central hypertonus, spasticity and rigidity, e. g., the distribution and nature of the palsy, the associated deformity, the character of the hypertonicity and the alteration in reflex activity, may be explained on the basis of their relationships to the neokinetic and paleokinetic systems. Of special interest is the apparent preponderance of the disk system or sarcostyles in neokinetic motility as contrasted with that of the sarcoplasmic function which predominates in paleokinetic motility. This suggests that the more highly specialized forms of movement may be associated with an increased functional activity of the disk system.

Policy of Ostrich (Venereal Disease Regulation). J. G. Adami.—p. 98.
*Life History of Ascaris Lumbricoides. F. H. Stewart.—p. 102.

Etiologic Relationship Between Herpes Zoster and Varicella.—Three cases are cited by Low which seem to show that there is some relationship between herpes zoster and varicella, that the virus of varicella might in certain circumstances, instead of producing a generalized eruption, cause a zoster eruption. He calls attention to the fact (1) that herpes zoster in a household is frequently followed by a case of chickenpox, (2) that cases of chickenpox may be followed by cases of herpes zoster in the same house, and (3) that cases of herpes zoster, in addition to the ordinary lesions, may show an eruption similar to chickenpox, so that one is almost forced to conclude that these two diseases are probably due to the same virus.

Relationship of Albuminuria and Casts to War Nephritis.—Among 50,000 men whose urine was examined, the total percentage of albuminuria (unaccounted for by pus, spermatozoa, blood, etc.) was found to be about 5 per cent. The average percentage of urines found to contain casts was 1.87; of this number 0.84 per cent. had definite epithelial casts, while in 1.03 per cent. hyaline casts only were found. MacLean is fairly certain that at least 132 cases of definite nephritis were returned from among the group of 50,000 men previously examined for albumin. As certain of the other twenty-nine cases were also, probably, suffering from nephritis, the total 161 cases may be taken as the maximum number of individuals who developed nephritis within nine months after being examined at the base. Out of the 161 patients returned as nephritis or albuminuria, only twenty-eight suffered from albuminuria just before going to the front. Of these, seven had epithelial and hyaline casts, while eight had hyaline casts only. Thus, out of the total 161 returns only 17.4 per cent, had albuminuria when examined a few months before they developed nephritis, while only 9.3 per cent. had both protein and casts.

Taking all these results together, it is contended by MacLean that the great majority of the cases that return from the front area as war nephritis do not show albuminuria a few months before contracting the disease. It would, therefore, seem that previous albuminuria plays little or no part in the etiology of war nephritis. The disease arises de novo, and is not an aggravation of some preexisting kidney defect the presence of which can be ascertained by any of the ordinary methods of examination.

Life History of Ascaris Lumbricoides.—Summing up our present knowledge of the larval development of this worm, Stewart says it has now been established that the ripe eggs of ascaris will hatch in the intestine of man, the pig, rat, mouse and guinea-pig, that the larvae enter the blood stream of the host, pass through the liver and heart to the lungs, there migrate from the capillaries into the alveoli, and thence through the bronchi and trachea to the pharynx. They reach the lungs and trachea between the sixth and eighth day after infection. Further, in the mouse the larvae then migrate down the alimentary canal and are passed alive, but not active, in the feces from the tenth to the sixteenth day.

Differential Diagnosis of Amebic and Bacillary Dysentery from Blood.—In the differentiation of amebic and bacillary types of dysentery the two following reactions have been used by Findlay: (1) the iodin reaction in the polymorphonuclear leukocytes; (2) the production of nuclear pseudopodia in the polymorphonuclear leukocytes. Taken in conjunction, Findlay says, these two tests enable an accurate diagnosis of the type of dysentery at an early stage of the disease in at least 90 per cent. of cases. The occurrence of a well-marked iodin reaction without the formation of nuclear pseudopodia is suggestive of a bacillary infection, while the absence of the iodin reaction and the presence of nuclear pseudopodia naturally point to an amebic origin. Should a well marked iodin reaction occur in conjunction with the formation of nuclear pseudopodia, the possibility of a mixed infection should not be overlooked.

Postinfluenzal Hemoptysis.—As a rule, the hemoptysis in influenzal cases commences toward the end of the illness, when there is a slight cough, an increase in weight, and no great tendency to wasting. The sputum shows a bright red staining, and not the typical rusty tint of acute pneumonia. Pneumococci are the predominant organisms and tubercle bacilli are absent. The characteristic physical signs are generally marked by their bilateral posterior distribution in the suprascapular areas, where breath sounds are faint and moist granular adventitious sounds are abundant, with no bronchial breathing and some bilateral impairment of the percussion note. The corresponding areas in front show little or no change, except some lack of resonance on percussion. The mid area of the lungs posteriorly is fairly clear, but the bases show congestive crepitation on both sides. The temperature, for a time, is irregular and fluctuating, and the pulse rate not so rapid as would be the case in a tubercular bacillary toxemia corresponding to similar physical signs. Careful observation of these cases for a few weeks will show subsidence of physical signs and temperature, with increasing weight and improved general condition. If, therefore, with slight hemoptysis the physical signs are bilateral and chiefly marked posteriorly, Wilson urges that it is well not to be too precipitate in diagnosing pulmonary tuberculosis, but to make frequent examinations of the chest and sputum while taking the general progress of the case into consideration.

Staphylococcus Aureus Septicemia Complicating Influenza in Malta.—The cases in which Staphylococcus aureus was found by Patrick were frequently those of a severe type of bronchopneumonia, with characteristic symptoms. The sputum of fifty patients with influenzal bronchopneumonia was examined bacteriologically. Nine of these fifty patients died, and *Staphylococcus aureus* had been found in the sputum of seven of them. The nine others who had shown staphylococcus recovered, though several had a severe attack. The amount of this organism grown from the sputum of the fatal cases varied, being sometimes a small growth mixed with other organisms, and once an abundant pure culture.

Simply Prepared Culture Medium for B. Influenzae.—Fleming emphasizes the advantages of blood altered in various ways on the growth of *B. influenzae*. He has had the opportunity of seeing and making many cultures of *B. influenzae* on agar with blood digested with trypsin. Wonderfully profuse growths can be obtained from its use. The preparation of the medium is, however, cumbersome, as it takes four or five days for the trypsin to produce the necessary change in the blood. It is thus impracticable to use such a medium if it desired to make cultures of *B. influenzae* without previous warning, unless a stock of the medium is kept on hand. It also requires sterile blood and sterile trypsin, which are not always to hand. Therefore, Fleming devised a medium which could be prepared on the spur of the moment.

If blood is added to a tube of agar and boiled for one minute the whole of the coloring matter of the blood and the coagulable protein is precipitated in masses. The tube can then be sloped, and before the agar cools sufficiently to become solid, the whole of this precipitate will have settled to the bottom, leaving the upper part of the medium clear. If *B. influenzae* is planted on this, an enormous growth results. The same result is obtained if blood corpuscles only are used. If 1 c.c. of blood is boiled with 9 c.c. water, the whole of the coloring matter of the blood and the coaguable protein is precipitated in masses which separate rapidly, leaving a clear, colorless, watery fluid. This fluid is added to liquid nutrient agar and sloped. On planting with *B. influenzae* a very profuse growth takes place. If to blood is added an equal volume of a normal solution of one of the strong mineral acids, such as sulphuric acid, the red color is immediately changed to brown by the breaking down of the hemoglobin. If an equivalent volume of normal caustic soda is added, a brown precipitate is formed and a brownish fluid separates. If this fluid is added to liquid agar, it furnishes a medium on which the most profuse cultures of *B. influenzae* can be obtained. It would appear, therefore, that so far as the growth of *B. influenzae* is concerned, sulphuric acid will effect the same change in blood in less than one minute that it takes trypsin four or five days to produce.

From the media described above very good emulsions of the bacillus can be obtained for agglutination purposes. By the addition of brilliant green to the medium, pneumococci, streptococci and staphylococci are inhibited to a much greater extent than is *B. influenzae*. Cultures of *B. influenzae* can be kept alive for a considerable period on a blood meat medium. The blood of all the patients tested by Fleming who were suffering from influenza agglutinated *B. influenzae*.

Pneumonia in Influenza. F. Rathery and David.—p. 653.
*Stereoscopic Photography of Tympanum. Molinié.—p. 655.
*Spirillum Gangrene of Lung. P. Nolf.—p. 657.

Photography of the Tympanum.—Molinié relates, without particulars, that he has ascertained the angle of incidence for photography at the shortest distance, and has thus been enabled to photograph the tympanum with minutest details, and make stereoscopic views of it. These views are invaluable for teaching otology, and may have forensic import at times, as well as serving for historical records of war aerial shocks, etc.

Spirillum Gangrene of Lung.—Nolf has previously reported cases of fetid bronchitis due to spirilla and he here adds another to the list. The spirillar bronchitis followed influenzal bronchopneumonia, and necropsy revealed gangrene of the inferior lobe of the left lung. The microbe involved was probably an ordinary spirillum from the mouth or pharynx. There were evidences of pyorrhea alveolaris.

*Healing of Wounds. T. Tuffier and R. Desmarres.—p. 1.
Early Suture with War Fractures of Long Bones. G. Picot.—p. 15.
Suspension for Fractured Femur. Antoine and Masmonteil.—p. 22.

Healing of War Wounds.—Tuffier and Desmarres made a special study of the rate of healing in thirty cases of war wounds, applying various disinfectants, etc., with chart records showing the units of healing day by day. They found a marked tendency to separation into two phases. In the first phase, the destruction of the microbes is imperative, and everything to favor this is demanded. But when the microbes are once conquered, there is no further need for disinfectants, and their main effect then is to damage the delicate tissues forming in repair. Merely a dry absorbent dressing is called for then, but systematic exposure to the sunlight in their cases much shortened the period of healing. In some of their cases the healing expectancy of thirty-five days was shortened by fifteen days by heliotherapy.

The "Vertigo That Restores Hearing."—Lermoyez has encountered a number of cases in which the ear had evidently become congested, and there was a tendency to tinnitus while the hearing grew less and less to apparently complete deafness. Then suddenly there was an attack of extreme dizziness, and as this passed off it was found that the hearing was approximately normal once more. He describes in detail three cases of the kind in men from 38 to 50. The mechanism seems to be like that in the foot when it "goes dead" from angiospasm, the result of extreme cold or emotional stress. The toes grow white and there is no feeling in them. But if the limb is rapidly heated, the blood rushes in, the toes grow red, and formication and sharp pain follow. For the latter, the French have a term, *onglée*. The inrushing blood restores conditions to practically normal and there is no further angiospasm. It is liable to recur, however, under the same circumstances.

Some of his patients had had a number of recurrences of the whole set of symptoms, the deafness and the sweeping away of the deafness, with the *onglée* of the labyrinth. The gradual obstruction or closure of the internal auditory artery entailed the progressive anesthesia of the ear, that is, the deafness. When the spasm suddenly subsides, the blood rushes into the labyrinth, and this sudden flood of blood which, in fingers and toes produces a sharp pain, in the labyrinth induces the special pain of the cochlear organ, manifested as tinnitus, and the special suffering of the vestibular apparatus, which is manifested as vertigo. It puts an end at the same time to the anesthesia of the ear, that is to say, to the deafness. The set of symptoms is exactly the reverse of what occurs in Menière's disease. With the latter the hearing is good; then comes sudden vertigo, and after this the gradual decline of the hearing. With the vertigo which Lermoyez describes, the hearing gradually grows poorer and poorer; then comes a severe attack of vertigo, and hearing is restored. The paroxysmal character of these disturbances excludes a permanent lesion like a hemorrhage. One of his patients sought voluntarily to bring on the attack of vertigo by whirling and loud noises, knowing that the attack restored his hearing for a certain time. In two women of 45 and 70 there seemed to be a combination of deafness of the Menière type along with deafness of the Lermoyez type.

Neuroses of the Diaphragm.—Denéchau refers in particular to cases of "big belly" or accordion abdomen in soldiers. His illustrations show the special type of distention as the result of derangement of the innervation of the diaphragm. In fully two fifths of his cases the label of tuberculous peritonitis had been affixed. The diagnosis is very simple if the possibility of a neurosis of the diaphragm is suspected. Treatment should be as for neuroses in general.

Septicemia from Phlebitis.—Dehelly reports a case which shows that septicemia may not be actual infection of the blood but may be merely the result of the pouring into the circulation of germs from some single focus. In his case this was an unsuspected phlebitis in the stump after amputation of the leg. When a second amputation was done higher up, thus cutting off the focus, there was no further septicemia. The discovery of the focus of phlebitis in the amputated segment of the limb was a surprise.

Drainage of the Pleura.—Chevrier's thirteen illustrations show the inefficiency of the usual modes of draining the pleura, and the superiority of the technic he describes, with the drainage provided at the very lowest point of what he calls the *vertébro-costale gouttière*, that is, the gutter formed by the curve of the ribs as they join the spine, the subject lying on his side or back. He first makes an exploratory incision and afterward a second purely for drainage, at the point where he has worked his finger through the first incision down to the very lowest point of this lowest space. He sends medicated vapors through from one incision to the other as the easiest means for sterilization of all recesses, and extols this combination as the best means for treatment of purulent pleurisy. A pleurotomy cannot be depended on to drain effectually except in the angulocostal line at the bottom of the vertebrocostal gutter, and at the very lowest point of this gutter, the patient lying on the sound side.

Duration of Biologic Phenomena after Introduction of Foreign Substance into the Organism.—Ambard comments on the great variability of the phenomena which follow the introduction of drugs or immune serums into the organism, and remarks that the ureosecretory coefficient allows these phenomena to be studied with much precision when the substance introduced passes out through the kidneys practically unmodified. For drugs, this eventuality is constant; for immune serums it is only hypothetical. The smallest dose of a drug that displays any apparent action, the liminal dose, as he calls it, must be reached before we can estimate the duration of its action. For example, if 0.20 gm. is the liminal dose of theobromin, and if 2 gm. is ingested at one dose, then the duration of its action will be the time necessary for elimination of 2 gm. minus 0.20 gm., that is, 1.80 gm. He reports research along this line from which emerges the law that the absolute value of the liminal dose is the principal element which determines the duration of the action of a drug. When more than ten times the liminal dose has been surpassed, the duration of its action increases very little, even for doses very much larger. The ureosecretory coefficient has been applied to the study of urea, ammonia, iodin, glucose and glycerin, and now Ambard has applied it to the study of the immune substances in so far as they are eliminated by the kidneys. This research has given him a new conception of anaphylaxis, as he describes. He now regards it as a sudden disintoxication. It is analogous to the phenomena observed when a morphin addict is suddenly deprived of morphin, only that in the latter case the disintoxication of the centers is accomplished by the kidney functioning alone, while in anaphylaxis the disintoxication of the centers is due to the drawing out of the toxic substances fastened to the centers. This drawing out of the toxic substances is done by another substance which has an affinity for them. This auxiliary hypothesis of the anaphylactic shock is the logical outcome of mathematical calculations, and it explains how a small preliminary dose of the immune serum wards off the anaphylactic shock by rendering the transition less abrupt.

Color Scale for Roentgen Exposures.—Nogier describes the Bordier chromoradiometer and states that he has used it in thousands of cases since 1906, and has always found it reliable. It is the only gage of the kind which is based on a scientifically defined unit. This unit should be substituted for the inexact methods in vogue otherwise, and particularly for the unit H. The unit used by Bordier is the amount of the rays which are capable of setting free 0.1 mg. of iodin in 1 c.c. of a 2 per cent. solution of iodoform in chloroform in a thickness of 1 c.c. shaded from the light. The dose of the rays is estimated by a pastille reagent of platinocyanid of barium. This is placed on the skin and the tint compared with the units of the color scale of the Bordier radiometer.

Regional Anesthesia for Amputation of the Breast.—Labat presents an illustrated description of the technic for infiltration of the skin and blocking the brachial plexus and the intercostal nerves, plus subcutaneous infiltration of the whole vast field of operation.

**Influenza. H. Sahli.—p. 1.*
*Lymphosarcomatosis and Leukemia. K. Schnyder.—p. 18.

Treatment of Influenza.—Wanner insists that the physician can do much to hasten recovery in influenza, helping to ward off complications on the part of the lungs and heart, to stimulate repair in lung and pleura, and promote the action of the whole apparatus of defense. This principle once recognized, each can apply it as he thinks best. When the patient has high fever and intense congestion from the start, Wanner gives hot drinks in abundance, and wraps in a large cold pack renewed every two hours. When the temperature has been reduced to 39 C., he gives hot packs instead of cold ones, with cataplasms, cupping, etc. He seeks to realize by these measures hyperemia in the organs racked by the disease. None of Wanner's patients with simple bronchitis complicating influenza died except one man of 70 with emphysema and enlarged prostate. The patient must have plenty of space; the wards must not be allowed to become crowded, and, above all, no case of pneumonia must be left in contact with cases of simple influenza. The light cases, the pneumonia complication cases, and the convalescents should all be in separate wards. When an influenza patient developed pneumonia, Wanner found that those around him developed it too, or the effect was seen in a peak in the temperature charts even when there were no durable results. He had a number of cases of pneumonia in which relapses occurred when the patients seemed to be well on the way to recovery but had been left in the same room with other cases of florid pneumonia. After these experiences, he made a point of removing the convalescents as soon as possible from contact with florid pneumonia. From the standpoint of contagion, the bronchopneumonia of influenza seems to behave like that of measles or whooping cough.

The damage from the toxins on the heart and circulation has to be combated at once. Camphorated oil in large doses should be given early, possibly digitalis, or caffein. The packs, cataplasms and cupping aid in the resorption of the exudation in the parenchyma of the lungs. Many patients with double pneumonia were thus tided past the danger point. One woman was brought in with bilateral pneumonia, dilatation of the heart and intense cyanosis, and was at the fifth month of pregnancy, but she left the hospital the twenty-fifth day, completely cured, the pregnancy continuing apparently unmodified. In the intensely toxic cases with a tendency to paralysis of the vasomotor centers, he found the effectual treatment was with epinephrin. Subcutaneous or intravenous injections of 0.001 gm. several times a day kept the pulse going well but did not modify conditions in the lungs. A fixation abscess seemed to do good service in some cases.

Industrial Poisoning of the Eyes.—Ammann reports injury of the eyes of certain workmen in a shoe factory from a substance used as a substitute for acetone oil in making patent leather parts of shoes. The injurious element in the new substance seemed to be chloracetone. In another establishment, a dye works, ammonium persulphate had been used instead of the usual sodium chromate. None of the workmen experienced any ill effects, but the proprietor developed a vesicular eruption on the skin, and blisters on the corneas. The man from whom the chemical was bought also displayed the same idiosyncrasy to the vicinity of the chemical, but the men handling it escaped. Ammann also describes a case in which ptomain poisoning from rotten beef caused ulceration of the cornea and fatal gastro-intestinal intoxication in one man. His son survived the intoxication, but he also developed ulceration in the cornea, reducing vision permanently to 1/25 right and finger counting at 20 inches left. Pflüger has published a similar case from eating spoiled cheese. Hegner has also reported a case of necrosis of the cornea after injections of salvarsan. Wessely and Köllner injected an alien serum intralamellar in a rabbit's cornea and parenchymatous keratitis developed. The incubation period of from five to nine days was the same as in Ammann's ptomain poisoning case.

Influenza.—Sahli proposes a theory in explanation of influenza which, he says, is found exclusively on facts. These facts are that bacteria seem to thrive better in mixed cultures; that influenza seems to be a mixed infection in the widest sense of the term; that the virulence of bacteria is influenced by other bacteria; that the virulence is enhanced by the receptivity of the organism—in other words by repeated passages through the animal body; that there may be a specific individual receptivity; that infections and especially droplet infections do not occur with a single bacterium but always with a number of bacteria, which are often of mixed species; that these mixed bacteria are liable to form a complex virus; that mixed cultures are liable to separate and turn into a single culture—both in the living body and in the test tube; that the main, the trunk epidemic may branch into various diverging subsidiary epidemics—these are all established facts, and especially well established for influenza. They explain influenza to be an obligate complex infection. The pneumococcus, the streptococcus, the influenza bacillus—possibly still others—form the obligate group, a symbiosis, a higher unit, which infects the organism as a unit. After infection has occurred, one or the other member of the group may develop preferentially. In one of his cases the sputum was swarming with influenza bacilli one day, and the next day the sputum was a thick pure culture of the pneumococcus. The complex virus, in twenty-four hours, had become completely transformed in the course of the single infection. This theory of an obligate complex virus throws light on the various features of influenza, as Sahli explains in detail. If an ultramicroscopic germ should yet be discovered, this would not invalidate the theory, but merely add another member to the group forming the obligate complex virus unit.

Lymphosarcomatosis.—Schnyder analyzes the special features of a case of generalized lymphosarcomatosis in a youth of 17 with lymphatic leukemia. A large tumor in the mediastinum, possibly originating in the thymus, with metastasis in lymph glands, kidneys, liver, gallbladder and dura, was accompanied by diffuse hyperplasia of the tonsils and base of the tongue, suggesting a leukemic or pseudoleukemic process. Similar findings were evident in the spleen.

*Congenital Syphilids in the Lungs. A. F. Canelli.—p. 11.
*The Blood in Infantile Sepsis. G. Milio.—p. 33.

Children Successfully Vaccinated Against Scarlet Fever.—Di Cristina's further experience has apparently confirmed the efficacy of the serovaccine obtained from the desquamated scales of scarlet fever patients. They seem to contain an antibody which, he says, appears to ensure immunity to the disease when injected subcutaneously. Horses treated with it developed antibodies in their serum to an amboceptor power of 2,000. For details of the technic he refers to his communication in 1916 (briefly summarized in The Journal, Sept. 30, 1916, p. 1049). Of forty children immunized by this means and left in the same room, sleeping in the same bed, with scarlet fever patients, not one contracted the disease. Of twenty-five children in families where there was a case of the disease, not one contracted it, and no case of scarlet fever developed in the hospital wards after the disease had been imported. Di Cristina and Pastore now announce that the method has stood so many tests that this immune prophylaxis against scarlet fever can be applied on a large scale. They have never witnessed any by-effects from it except very rarely a slight fleeting eruption—evidently an anaphylactic phenomenon—which might suggest scarlet fever if it were not for its rapid subsidence and the absence of all throat symptoms and fever. The children thus immunized have been followed for six months, and the continued presence of the induced amboceptors has been confirmed to date.

Palate Sign of Inherited Syphilis.—Tanturri has noticed that with inherited syphilis the edge of the soft palate as it arches over to the uvula has a characteristically irregular outline. Instead of forming a smooth edge, it looks dentated, as if both epithelial tissue and mucosa had been eroded. There may be loss of substance for 1 or 2 mm. from the edge, but the flexibility of the parts and the color are not modified. Those presenting it were of all ages, from the newly born to 20 years old, and he asserts that this eroded outline of the palate arch on both sides may be accepted as positive testimony to the existence of inherited syphilis. In seven newly born, with serious manifestations of inherited syphilis, this lacelike outline of the palate was exceptionally pronounced.

Congenital Syphilitic Lesions in the Lungs.—Canelli analyzes the literature on this subject, with three pages of bibliography, and describes the various types of syphilitic changes in the lungs. They are practically always fatal.

The Blood in Sepsis in Infants.—Milio's research on four healthy infants and on eleven with sepsis demonstrated that the blood in sepsis shows leukocytosis but not always polynucleosis. The specific gravity was found increased in 70 per cent. of the infants; the viscosity is reduced but coagulation occurs sooner than in normal blood. There does not seem to be any change in the percentage of water.

Present Status of Surgery for Internal Hydrocephalus. E. Aievoli. —p. 1019.

Action of Chloroform on Suprarenals.—Aloi's experiments confirm that chloroform induces increased production of epinephrin in the suprarenals. The epinephrin is poured out into the circulation, so that the suprarenals in this phase seem to have become exhausted and show very little epinephrin.

Gallstones and Hypercholesterolemia.—Fedeli and Torri have been conducting research with the mineral waters at Montecatini which are noted for their action in cholelithiasis. The metabolic findings and the course in six cases under the influence of the waters are reported in detail. The cholesterol content of the blood was much increased in all, and in every case it sank to normal figures under the influence of the spa treatment. Experimental research confirmed the clinical findings; all testifying that the saline-alkaline waters stimulate the secretion of bile; the less concentrated of the waters are more effectual in this respect, rendering the bile more fluid. This in turn helps to wash out the cholesterol, and the cholesterol content in the blood declines. At the same time the waters modify the general metabolism.

Annaes Paulistas de Medicina e Cirurgia, S. Paulo

*Urinary Amebiasis. T. Bayma and A. Fagundes.—p. 173.

September, 1918, **9**, No. 9

*Typhoid Meningitis. A. P. U. Cintra.—p. 193.
*Nasal Diphtheria. P. Santos.—p. 202.

Vaccine Treatment of Pertussis.—Bayma was skeptical as to the efficacy of the autogenous vaccine prepared by Kraus from the sputum of whooping cough patients, but his experiences with this "antitossina" soon converted him. He made the vaccine from the whole sputum instead of using—like Kraus—merely the threads of mucus. His official report states that in the forty-seven cases given this treatment a cure was realized, and that it is to date the most effectual means for treating whooping cough yet known. This is his dictum from experience with hundreds of cases, and from the experience of others. Fully 3,500 c.c. of this vaccine was prepared at the Institute of Bacteriology, in his charge, and 2,200 c.c. of it was used by other clinicians.

Urinary Amebiasis.—Bayma and Fagundes relate that in the course of 1918 they found amebas in the urine from three patients. The total absence of symptoms from the bladder in two cases suggests fecal contamination of the urine. In the third case there was severe acute cystitis, and living amebas were found in both urine and stools. Epinephrin was given by the mouth (Bayma's method), and the bladder was flushed with the 1 per thousand solution. The bladder functioning promptly returned to normal, confirming anew, they say, the potency of epinephrin in human amebiasis.

Typhoid Meningitis.—Cintra reproduces Bayne Jones' tabulation of seventeen cases of purulent meningitis of typhoid origin, and adds several more he has compiled and one case from his own experience, bringing the total to twenty-seven recorded since 1901. Seventeen were recorded before that; thus there are forty known cases to date. This complication may occur at almost any stage of typhoid, and a fatal outcome is the rule. In exceptional cases the meningitis may be the first manifestation of the infection. In this case the clinical picture is that of meningococcus meningitis, as in his personal case. The man died the second day, the fifth day of his sickness, and typhoid bacilli were found in the cerebrospinal fluid. The localization of the germs in the meninges may be facilitated by some predisposing factor. The Wassermann reaction in this case was positive and there were other signs of syphilis. In the twenty-seven tabulated cases all but two proved fatal. One adult recovered after an operation, the meningitis having been restricted to the lumbar region. Another recovered from a subacute meningitis. The list includes three cases of primary acute meningitis, including Cintra's case, without intestinal lesions.

Nasal Diphtheria.—Santos has found diphtheria bacilli in the nose of infants more often than in the throat, a primary diphtheria of the nares being comparatively common in infants exposed to infection. It is almost invariably mild, but it may be followed by secondary diphtheria of the throat, and the mild nasal diphtheria may give rise to severe diphtheria in others. Association with streptococci renders the outlook graver. He calls attention to nasal diphtheria to emphasize the importance of isolation, and the necessity for school physicians and others to examine the nose as well as the throat of children.

*Influenza in Porto Rico. F. del Valle Atiles.—p. 279.
Hydronephrosis from Calculus in Ureter. J. Avilés.—p. 286.

Influenza in Porto Rico.—Atiles relates that influenza appeared in Porto Rico in June soon after the arrival of a ship from Spain. It spread rapidly, and it is estimated that at one time fully 8 per cent. of the entire population had the disease simultaneously, and that 40 per cent. of the population were affected during the epidemic. Of the 250 physicians practicing in the island, 60 per cent. contracted the disease. All forms of the disease were encountered, from the mildest to the severest respiratory, gastro-intestinal and nervous forms, with predominance of the pneumonic type. The mortality was at least 2 per cent. In about 70 per cent. of the cases recovery occurred under serotherapy. The damage from alcohol given by the family against the physician's orders was particularly striking in the case of one girl with meningitis complicating influenza. Death followed almost at once. With the exception of serotherapy, treatment was only symptomatic; antistreptococcus serum proved very useful.

*Abdominal Pain with Incipient Pneumonia and Febrile Rheumatism. O. Clark.—p. 388.

Surgery in Syphilis.—De Mendonça discusses both surgery for syphilitic lesions and the influence of syphilis on healing after any operation. In case of doubt in regard to the nature of tumors in the anorectal region—which are often extremely difficult to differentiate and often prove refractory to specific treatment—it is better to remove them even if time should demonstrate that the operation was unnecessary, rather than expose the patient to danger of metastasis from a sarcoma. He describes seven cases of this type of anorectal syphiloma. One man of 30 applied for treatment of hemorrhoids. The rectum showed lesions suspicious of syphilis, and specific treatment was advised preliminary to any operation. The man refused and was operated on in another town. A few months later he returned with advanced rectitis with profuse purulent secretion, and he died within a few months, the diagnosis still in doubt. This was before the days of the Wassermann reaction. In a second, equally unfavorable case, the patient was a man of 21 and the rectum, perineum and cellular tissue of the lower portion of the pelvis formed a single agglomeration, studded with fistulas.

An operation was done on a man of 40 for stenosis of the rectum, in 1913, but the rectitis persisted and grew constantly worse. The man had a history of syphilis but the Wassermann reaction was constantly negative. Specific treatment brought great improvement in the general health but the rectum had to be resected. In another young man with rectitis and stricture, improvement to recovery followed an operation for hemorrhoids and slitting the stricture. One patient in the group was a woman of 38 with a syphilitic husband. With a temporary artificial anus and specific treatment improvement was realized. Some surgeons maintain that syphilis does not retard the healing of wounds, but Mendonça's experience has convinced him that syphilis, as well as other constitutional diseases, is liable to exert a most unfavorable influence on operations, especially laparotomies. In three recent cases, the laparotomy wound opened again, or there was dilatation of stomach and intestines. The Wassermann reaction was strongly positive, and under specific treatment healing proceeded further without mishaps. Other instances are reported of complications in skin, etc., developing after operations on syphilitics, all emphasizing the wisdom of a course of specific treatment before attempting any operation on syphilitics.

Vaccine Therapy of Influenza.—Da Cunha and his co-workers inoculated monkeys with blood and sputum from influenza patients after filtering through a Berkefeld or Chamberland F candle. The temperature ran up afterwards to above 104 F. in one of the monkeys. In a second monkey there was fever but not quite so high. The blood from influenza patients induced a febrile reaction when injected in guinea-pigs. Inoculation of two men and one monkey with Pfeiffer's bacillus cultivated from the influenza patients was always negative. The monkeys first experimented on were inoculated anew with the sputum filtrate, but without any temperature response. This and other facts cited suggested the feasibility of vaccine treatment of influenza, using the sputum filtrate for the purpose, as a vaccine containing the ultramicroscopic microbe. They have not applied this vaccine in prophylaxis in the human, but the experiments on animals seem promising, and Nicolle and Lebailly have reported successful experiments in this line.

The Blood in Yellow Fever.—Fraga agrees with Couto and Sodré that the cause of the jaundice in yellow fever is to be sought in the blood. It is not due to any special fragility of the reds but to their destruction by the extremely toxic yellow fever virus, acting probably on the lipoids of the corpuscle membrane, with possibly a hemolysinic hemolysis.

Abdominal Pain at Onset of Febrile Rheumatism and Pneumonia.—Clark relates several instances of acute articular rheumatism in children which began with a sudden and intense pain in the abdomen, the child saying the pain was like a blow. In other cases this sudden intense pain opened the clinical picture of influenzal bronchopneumonia. Pneumonia in one young man started with such distressing vomiting and intense abdominal pain that death seemed imminent, but he had quite recovered by the end of the second week. Pleurisy and pericarditis may start with intense abdominal pain, and two cases were published last year in which infarction of the heart simulated acute surgical abdominal conditions.

*Date of Fecundation. L. Razetti.—p. 232.
*Epidemic of Influenza. J. de D. V. Ruiz.—p. 233.

Date of Fecundation.—Razetti discusses the various theories in vogue and rejects all except those which accept the menstrual function as a preparation of the uterus for the embedding of the ovum. The internal secretion of the corpus luteum is what starts this preparation. According to this theory, there is no ripe follicle in the ovary during menstruation, and hence fecundation during this period is impossible.

Influenza in Venezuela.—Ruiz reviews his experiences at Macuto "during this terrible epidemic that is still keeping us in distressful armed expectation." The three other doctors in the town were down with the epidemic, and Ruiz had scarcely a moment's respite during those unforgettable days until the authorities sent from elsewhere other physicians to his aid. The eight deaths among 400 cases were of the septicemic type, with pneumonia under way before he saw them. He was impressed by the constantly slow pulse with good tension, in marked contrast to the extremely high fever, in all his cases except very young infants and the very old. A pulse of 54 to 85 accompanied temperatures up to 40 C. In certain convalescents from the thoracic form he found a pulse of 38 and 40 C. with a temperature under the tongue of 36 C. One patient, on the other hand, presented alarming tachycardia but it became transformed at once into bradycardia under a digitalis preparation. The slow pulse seemed always to be a favorable sign, as Ruiz has always found it associated with a good prognosis in yellow fever. It seems as if the virus causing the disease affected the medulla oblongata from the start. Strychnin was his main reliance for a tonic.

*Functional Retention of Urine. A. Pulido Martin.—p. 157.
Segmentation of Cadaver for Teaching Purposes. S. Sierra y Val.—p. 158.

Influenza.—Velasco remarks in these "Clinical Impressions" of the epidemic that influenza certainly confers immunity, as those who contracted the disease when it appeared in the spring escaped it when the epidemic flared up again in the fall, and vice versa. Another feature that impressed him was that the elderly usually escaped and when they did contract the disease it generally assumed a mild form in them. He noticed further that in every case in which there was intestinal hemorrhage, the outcome was favorable. The hemorrhages occurred between the twenty-fourth and sixtieth hours, presumably before ulceration could have developed. Some great change in the composition of the blood seems more probable.

Functional Retention of Urine in Woman.—Martin reports the case of a woman of 60, otherwise healthy, who every three or four years has had complete retention of urine lasting for four to six days, conditions then returning to clinically normal. The cystoscope revealed finally a minute papilloma, no larger than the head of a pin. This probably acted like a foreign body at times, setting up spasmodic contraction in the sphincter. It is possible, he adds, that closer search for some minute excrescence or lesion might upset the diagnosis of hysteria in a certain proportion of cases.

*Surgery for Chronic Constipation. G. B. Arana.—p. 437.
*Medical Treatment of Habitual Constipation. I. Ymaz.—p. 492.

Chronic Constipation.—Recently the Asociacion Medica Argentina held a three day meeting for a thorough discussion of chronic constipation from all points of view. Udaondo emphasized the frequency of stomach derangement, especially motor insufficiency, as accompanying constipation. There seems to be a rupture of the gastro-intestinal functional correlations. Hyperacidity was exceptionally frequent in his cases of chronic constipation, as well as other symptoms indicating a neurosis of the vagus. This may disturb the functioning at almost any point in the digestive tract, spastic conditions or atony hindering the normal passage of stomach and bowel contents, and entailing acidity. In a number of cases tobacco seemed to be responsible for the irritation of the nerves, as conditions righted themselves when tobacco was dropped. The deleterious influence of tobacco was particularly manifest in cases in which spastic colitis was the principal manifestation of the hypervagotony. Arana discussed the surgical treatment for pericolitis and megacolon, and reported eight typical cases with illustrations. Ymaz emphasized that rational medical treatment of habitual constipation is possible only when the exact cause has been ascertained. He reviewed the medical field and warned that a diet to give more bulk to the feces must not be carried to extremes, as too large a quantity of indigestible tissues probably injures the mucosa more than a mild chemical stimulus. Morena remarked that pericolic membranes are a frequent finding at necropsies of children with a tendency to so-called chronic appendicitis. He has encountered in children all kinds of pericolitis and abnormally large cecum, colon, etc., and in nearly every instance there were attacks of pains or a chronic pain. But very seldom did these children display any tendency to chronic constipation. These findings sustain the assumption of the frqeuent congenital origin of these lesions.

*Radium for Cancer of Upper Air Passages. R. Botey.—p. 275.
*Bronchopneumonia in Children. E. Suñer.—p. 289.

Radium Treatment of Cancer of Upper Air Passages.—Botey gives an illustrated description of his methods for using radium. His experience has been that superficial epithelioma of the nose has usually been completely cured by six exposures of from thirty to sixty minutes each, at intervals of from four to seven days. His results were mediocre with epithelioma of the cheek and in the nose. There is no doubt that in treatment of cancer of the larynx small doses of radium with long exposures are not nearly so effectual as large doses for a few hours. But these large doses, even for a short period, induce such a secondary reaction that the method has to be abandoned. If the radium could act alike on all the cells of the cancer, the cure would be complete, but the deeper lying cells are not destroyed, and the effect on them is only to stimulate them. Metastasis and recurrence are more frequent than after a radical operation. The latter if done early, before there is glandular involvement, is still as ever, he reiterates, the best treatment. Radium treatment after operation aids in warding off recurrence. Radium applied directly to a cancer in the esophagus improves conditions for some months but the disease continues its course. In the upper air passages and larynx, superficial cancers not extending into the depths may be completely cured, especially if the radium tube can be buried in the mass of the tumor. Adenomas are the most amenable.

Bronchopneumonia in Children.—Suñer ascribes great differential importance to the continuous dyspnea with bronchopneumonia. When the dyspnea is due to the fever alone, and not to the lung or heart, the child may hold its breath a moment during auscultation. When it does this, it is a favorable sign as to the state of the lungs. Treatment of bronchopneumonia in children is mainly by hygiene and physical measures.

Palography. A. Mut.—p. 347.
*Fibrous Forms of Pulmonary Tuberculosis. G. Triviño.—p. 355.

Early Diagnosis of General Paralysis.—Salazar remarks that there are no somatic signs which can be relied on to differentiate incipient general paralysis from neurasthenia. But he affirms that this is possible by study of the modifications in the mental processes. He has had a number of cases in which general paralysis developed under his eyes. As the dementia affects all the mental processes, the replies to any kinds of questions will soon reveal the mental impairment. He discusses in turn means to test the mental processes, the will power and the affections, and to elicit evidences of changes in them which will differentiate the cases at once from neurasthenia.

Fibrous Forms of Tuberculosis.—Triviño concludes his study of chronic fibrous pulmonary tuberculosis by emphasizing that a slow pulse in chronic tuberculosis is an eminently favorable sign. He urges that the pulse should be regularly recorded. When the pulse keeps at the same rate without change, and if there has been only brief and transient hemoptysis and fever on certain occasions, and if the general health keeps good, the pulmonary process is evidently of a fibrous type, and long survival may be anticipated provided the rules of hygiene are followed.

*The Mission of Medical Societies. J. G. Salazar.—p. 113.

The Pathology of Speech.—Torres here concludes his study of the *patologia del lenguage* in paranoiacs, laments and other grades of mental impairment. He remarks that a man under the influence of liquor runs the entire gamut of the pathology of speech. We see in a demonstrative and well defined epitome the entire involutive process of speech and the brain processes inspiring it. Starting with transient phases of exaltation, even brilliancy, the mental synthesis grows less and less, to absolute dementia, the man's utterances reproducing the mental and organic degeneration which induces the dementia during the brief period while the alcoholic intoxication lasts.

Arsphenamin versus Neo-Arsphenamin. — Vasconcelos relates that notwitstanding the general opinion that neo-arsphenamin is superior to arsphenamin, his experience has been that the latter is more effectual. He reserves neo-arsphenamin for patients with heart or vascular lesions or tendency to hemorrhage, or with veins difficult of access, or the very nervous. Also for children and when the drug has to be administered by the rectum. For treatment of infants, injection into the colon is the preferable method, he thinks.

Subcutaneous Injection of Oxygen.—Lope extols the advantages of subcutaneous injection of oxygen in cases of asphyxia, this simple but potent measure serving to recall to life many patients otherwise beyond relief. He reiterates that these injections are absolutely harmless, while the whole procedure is so simple that any practitioner can apply it. The oxygen is absorbed by the blood, and the relief was immediate in the case in which he applied it first, six years ago; the patient in advanced Bright's disease, suffering from recurring attacks of most distressing dyspnea. After injection of 150 c.c. of pure oxygen the improvement was so prompt and so marked that since then Lope has not hesitated to use this simple but heroic measure at need. In certain cases of asphyxia and dyspnea, inhalation of oxygen does not aid in the regeneration of the blood because the inflammatory process and its products in the air passages, or paralysis of the circulation in the lungs, may prevent absorption of the oxygen. It is in such cases that the oxygen injected into the blood proves a life saving measure. It has been advocated for certain other conditions, but he has applied it only in dyspneic states, including the dyspnea with operative or induced pneumothorax. A Pravaz needle with tube to connect it with the oxygen tank is all that is needed in an emergency, but it is better to have a graduated receptacle for the oxygen interposed between the douche can and the needle, with pinchcocks on each tube. By raising the douche can, the graduated jar fills with water; then the douche can is lowered, and the water flows back into it, thus aspirating the oxygen from the tank into the graduated jar. When it is full, the tube is disconnected with the tank and the needle is placed on the tube ready for the injection. The apparatus is illustrated. He advises keeping it charged and ready for use in hospitals or when conditions are liable to require it elsewhere.

The dyspnea subsides, the cyanosis disappears, the fever is reduced, respiration and pulse grow slower, the headache improves or subsides and the patient feels immeasurably better. The improvement may be transient or it may prove permanent. He was called one night urgently to a man of 70 with severe pneumonia and bad heart, who was lying unconscious on the floor near his bed, the cyanosis extreme, the pulse scarcely perceptible, the suffocation alarming. In a few minutes the oxygen injection was made without disturbing the patient as he lay on the floor. About 200 c.c. of pure oxygen were injected under the skin of the right flank. The impressive picture then was presented of actual return to life. In less than fifteen minutes he was sitting up, smiling, in bed, the livid tint all gone. He lived a year and a half longer. Certain writers advocate these injections in treatment of bronchopneumonia and in whooping cough.

Chloroform in Tuberculosis.—Olivares warns that a general anesthesia with chloroform seems to have a decidedly unfavorable action on incipient tuberculosis, whipping it up to a more rapid course. He relates three typical instances of this. Suspicion of tuberculosis should warn against the use of chloroform on account of its depressant action on the liver, etc. If chloroform has to be used, as little as possible should be given and for the shortest time possible.

The Mission of Medical Societies.—Salazar comments on the value of organization and cooperative research. The work of the individual, however meritorious it may be, cannot bear such fruit as when it is brought before others for criticism and stimulation. Especially in Mexico, he says, the diseases peculiar to the country have never been adequately studied. The medical lore and art are European, and it is a question how far they can apply to Mexico, as they were designed for a different country and a different people. It is scarcely known that tabardillo is not exactly the same as exanthematous typhus, that goiter is due to the water, that *mal del pinto* is very prevalent on the Pacific Coast. Medical societies usually dally with fragments of all kinds of subjects, instead of linking up a series of researches which would amount to something definite and valuable.

*Enteralgia. R. del Valle y Aldabalde.—p. 193.

Pathology of the Skin in Connection with Internal Pathology.—Oyarzábal explains how impermeability of part of the lung entails hyperemia as the blood piles up against the obstacle. This hyperemia entails catarrh and bronchial secretion which in turn hamper the respiration and heart action. With cyanosis under these conditions, it is difficult to know whether the reduction in the respiration area or the venous stasis is responsible for it. Acute endocarditis, on the other hand, is often secondary to pustules, abscesses, or other processes inducing embolism in the vessels of the skin. Certain small vessels may thus be completely obstructed although the skin may show no signs of it. Embolism in the vessels of the liver may induce jaundice. The cheeks may be red and full but an experienced eye will detect a faint bluish tinge to the red, the first manifestation of heart disease. The circulation is growing sluggish so that the blood does not get fully oxygenated. The obstacles to free circulation of blood lead to stretching of other vessels and the stretched walls let the fluid through and edema results. The lymph plays only a subordinate rôle. The edema with heart disease obeys the laws of gravity, while the edema with nephritis may develop at other than the lowest points. With exophthalmic goiter, there may be a sensation of heat in the skin and profuse sweating. There is also a marked reduction in the resistance to the electric current. This may occur also with sclerodermia and myxedema. In certain cases of exophthalmic goiter the skin resembles the skin of myxedema.

Enteralgia.—Del Valle's patient is a business man with habitual good health who at the age of 41 had pain in the left iliac fossa without fever or vomiting. This pain has recurred at times during the seven years since rebellious to treatment. Worry over his tuberculous child had evidently induced an extremely nervous condition, and there is also probably some subacute inflammation, too slight for detection by palpation but enough, in connection with the extreme nervousness, to explain the rebellious enteralgia. These pains of mixed origin—a slight local lesion and tendency to neurosis —do not spread like ordinary pains along the nerve track nor do they radiate in special directions. The treatment should be directed mainly against the neurosis. As this subsides, the insignificant local lesion gets a rest and may heal at once.

Treatment of Pneumonia in Children. B. H. Briz.—p. 921.

Catheterization of Arteries and Veins.—Goyanes comments on the important information to be derived from catheterization of arteries and veins in animals. In the clinic it is possible by this means to introduce a drug so that it will have an immediate and direct action on the focus. Local anesthesia can likewise be induced by way of the artery (Goyanes' method) or by way of the vein (Bier's method). In one case of extremely severe puerperal infection, he introduced the catheter into a collateral of the femoral artery in the triangle of Scarpa, pushing the tip of the catheter into the aorta above its bifurcation. Then the femoral arteries on both sides were vigorously compressed and a solution of a silver salt was injected through the catheter. It had to pass through the internal iliacs and spread thence throughout the whole of the infected visceral region. Goyanes has also introduced a large catheter into an artery to plug it and thus shut off the blood from the field of operation below. He thinks he was the first to apply on man this method of shutting off the blood for a major operation. In one case an extensive osteosarcoma of the root of the right thigh, involving the pelvis, with ulceration but no obliteration of the arteries, seemed to have originated in the greater trochanter. The tumor had been noticed for ten years and had grown rapidly to a large size in the last eighteen months. A catheter slipped into a condom was introduced into the femoral artery and pushed up to the aorta. Then the condom was distended with a few cubic centimeters of saline. At once the pulse stopped in all the arteries of the sound leg. The catheter was then withdrawn a trifle, after collapsing the condom by letting the fluid in it run out. The pulse then reappeared in the sound limb, showing that the obstruction now was only in the common iliac artery, and the condom was distended anew, completely plugging this artery. The femoral artery was then ligated just above the point where the catheter entered it, which held the catheter firm. The artery was thus firmly plugged, and the limb and nearly half of the pelvis were amputated, sawing the horizontal ramus of the pubis. The shutting off of the blood was so complete that the gluteal and sciatic arteries did not bleed when they were severed. The operation had to be so extensive that it made too much demands on the patient, long debilitated by the sarcoma, and he died ten hours later.

Influenza.—Marañon and his co-workers were sent to France to study conditions there, and they report that the prevailing epidemic is the same disease that has been prevailing in Spain. The therapeutic and prophylactic measures are about the same—nothing new and effectual has been discovered as yet. Vaccine therapy seems to offer the best promise.

Mercuric Chlorid in Influenza. A. J. D. van Twist.—p. 1826.

Reform in Medical Education.—In this fourth editorial on this subject, van Rijnberk quotes the views of Profs. W. H. Welch, F. P. Mall and C. M. Jackson on the aims and ideals of medical education and the best means to realize them.

Emergency Dressings.—De Mooy advises that instead of removing the clothing to obtain access to a wound, the part over the wound should merely be slit and turned back. Then after the wound has been dressed, the slit garment can be brought together over it, and be wound above and below with a strip of gauze. By this means, the dressing is fastened immovably in place. After an amputation, the leg or sleeve of the garment can be tied together below or turned back and fastened. By this method the wounded are spared the discomfort and chilling from stripping off of the garment. Seventeen small diagrams show the application of the principle to wounds in different regions.

Nephritis in Children.—Schippers and De Lange state that examination of the urine of 1,000 children at the Children's Hospital at Amsterdam failed to show any dependable connection between the presence of formed elements, of albumin or of chondroitin and the existence of nephritis in dubious cases. They occur with nephritis but they may also occur in the healthy. On the other hand, functional tests of the kidneys generally reflect the functional capacity of these organs, and they may be relied on to clear up the diagnosis. The two tests applied in the research reported were the accommodation test and the metabolic findings on the Hedinger and Schlayer test diet. The findings with these two methods are tabulated for comparison, filling three pages, as recorded for twenty-two children, ten with clinically normal kidneys and three each with orthostatic or atypical albuminuria or convalescing from acute nephritis or with paedonephritis. The latter is Heubner's term for a benign inflammation of the bladder without phenomena on the part of the vessels, but with a small number of formed elements in the urine and albuminuria, often of an orthostatic type. These tests revealed that one case which seemed to be mere orthostatic albuminuria proved to be strongly suspicious of nephritis, as also two cases, otherwise atypical albuminuria. The fluctuations found even in normal children warn, however, that the limit between health and disease is not sharply defined. Some of the children listed as normal may yet prove to have incipient contracted kidney, explaining the wide range in their supposedly normal condition.

They list further the findings when 0.5 gm. potassium iodid was given to the children in a wafer with a little water. After the fortieth hour the urine was tested regularly for iodin. In the normal children all the drug had been eliminated by the forty-first hour, probably from the twenty-eighth to the thirty-eighth hours. With one child with nephritis the elimination dragged along to the forty-fourth hour, as also in a case of paedonephritis, and to the forty-second hour with an atypical albuminuria. In all the other children tested no traces of the drug could be found by the fortieth hour. With the accommodation test, the subject drinks from 500 c.c. to 1.5 liters water and the glomerulus function is estimated by the time required for this mass of fluid to be eliminated. Adults may void 500 c.c. or more at the first micturition, and healthy kidneys eliminate the whole and as a rule even a little more, within four hours. The specific gravity falls to 1.002 or 1.001. The diuresis afterward is much reduced, and the specific gravity then reaches 1.025 or 1.030. The children are kept on the usual standard diet for their age for several days. The urine is voided at 6 and at 7 a. m. Then the child drinks 300 c.c. or more of water and nothing more is given to drink till 7 p. m. If it complains of thirst it is given an apple. At 11 a. m., 1 and 4 p. m. it is given a test meal of bread and biscuits, with cake, jam or cheese, but without butter, and at 7 p. m. it gets the usual food. The urine is collected separately at seven two-hour intervals and the amount, specific gravity and salt content are recorded for each specimen, to test the concentration as a tubuli function.

The research reported confirms the value of these two tests when confronted with a puzzling case of albumin or formed elements or chondroitin in the urine with nothing else to suggest nephritis. Repetition of the tests will usually throw light on the most puzzling cases, as the choice of a trade or profession or acceptance for life insurance cannot wait for time to clear up the case by the ultimate outcome. Pollitzer's test was also given a thorough trial and found not practicable. The findings with it demonstrated, however, the importance of extrarenal factors in the diuresis. The kidney functioning cannot be estimated apart from the organism as a whole.

*False Heredity. K. H. Krabbe.—p. 2005.
*Isolation in Influenza. H. Jensen.—p. 2012.
Reduction of Morbidity and Mortality Under Recent Restrictions on Alcohol. P. Heiberg.—p. 2013.

False Heredity.—Krabbe means by this term the development of disease in which the heredity of occupation is involved instead of inheritance of an organic pathologic tendency. The importance of recognition of the true cause is evident, as removal of the cause will put an end to the disturbances in this case, while it is not so easy to cure an organic disease. A specific instance is related, a man presenting intense tremor of the hands for many years, and finally his son developing the same tremor. The diagnosis wavered for some time between paralysis agitans, sclerosis in patches and pseudosclerosis. Krabbe parenthetically remarks that when there is any doubt, one can be certain that neither of these diseases is involved. The son at 33 developed the same symptoms as the father, and for nine years they were accepted as an inherited nervous disease. Then some one investigated the exact nature of the work of the two. They were listed as "instrument makers," but it was found that their business was to fill thermometers with mercury!

Importance of Isolation in Influenza.—Jensen had every person with influenza in his town strictly isolated from the first symptoms, the attendants wearing overgarments and masks. The epidemic thus was restricted to one case in each of ten families, and all but two were imported cases. The population is less than a thousand, but the houses are small and in some as many as ten persons sleep in one room.
